Growth habit, occurrence, and use. The genus *Laburnum* includes 4 species of deciduous trees and shrubs native to central and southern Europe (Krüssmann 1984; LHBH 1976; Scheller 1974). Laburnum species have been cultivated for centuries, primarily for ornamental purposes. Laburnum arches and walks are a popular feature in many large gardens (Wasson 2001). The species is adaptable to many soil types, including limestone, but prefers well-drained soil and light shade (Dirr 1990; Krüssmann 1984; Rudolf 1974). All parts of the plant, particularly the seeds, are poisonous (Krüssmann 1984; LHBH 1976). Seeds and other parts of the plant contain the alkaloid cytisine, which can be fatal to humans and animals (Dirr 1990; Greinwald and others 1990; Leyland 1981). The 2 species and a hybrid of interest are described in table 1.

Scotch laburnum is a small tree with a short, sturdy trunk and flat to round-topped crown; it is considered to be the superior garden species (Dirr 1990). Common laburnum tends to be a low branched, bushy, wide-spreading tree (Dirr 1990; LHBH 1976). Waterer laburnum, a natural hybrid between Scotch and common laburnums, is a distinctly upright, oval to round-headed small tree or shrub (Dirr 1990). The foremost laburnum in cultivation today is Waterer laburnum 'Vossii', a superior tree with dense habit, racemes up to 60 cm in length, and a tolerance of alkaline soils (Dirr 1990; Krüssmann 1984).

Flowering and fruiting. The perfect, ornate, golden yellow flowers are 1.9 cm long and are borne on 15- to 25-cm pendulous racemes; Scotch laburnum has racemes that are 25 to 38 cm (Dirr 1990). Flowers bloom from May to June, and the flowers of Scotch laburnum and Waterer laburnum 'Vossii' are fragrant (Hillier 1991; Krüssmann 1984). The fruit is a brown legume (pod), 5.1 to 7.6 cm long, with black seeds (figures 1 and 2) (Rudolf 1974). The legume of Scotch laburnum is winged, forming a knife-like edge (Dirr 1990). The seeds are tardily dehiscent, ripening from late August to October (Rudolf 1974). Each legume contains several black seeds (only 1 or 2 for Waterer laburnum 'Vossii'), and good seed crops are borne annually (Krüssmann 1984; Rudolf 1974).

Collection of fruits; extraction, cleaning, and storage of seeds. Legumes should be harvested from the trees beginning in September through November and spread out on flats in a shed or loft with good air circulation to dry (Macdonald 1986; Rudolf 1974). Newspaper should be placed over the legumes to prevent the seeds from being ejected away from the flats. Seeds are extracted by breaking the legumes by hand or by machine threshing (Macdonald...
The seeds and debris are separated by sieving or by using a directed flow of air. About 45 kg (100 lb) of legumes will yield about 11 kg (25 lb) of cleaned seeds (Rudolf 1974). The following values for number of cleaned seeds per weight for laburnum species have been found: Scotch laburnum, 31,966 to 35,004/kg (14,500 to 15,878/lb); common laburnum, 35,273 to 37,478/kg (16,000 to 17,000/lb); and Waterer laburnum, 40,917/kg (18,560/lb); with 85% germination and 90 to 99% purity, depending upon cleaning techniques (Allen 1994). The dried legumes may be stored overwinter in sacks placed in a dry shed or loft. Seeds stored dry in sacks will retain good viability for 2 years (Dirr and Heuser 1987; NBV 1946, cited by Rudolf 1974).

Laburnum seeds do not germinate readily unless the impermeable, hard seedcoat is ruptured by mechanical or sulfuric acid scarification. Mechanical scarification of common laburnum seeds resulted in 99% germination (Stilinovic and Grbic 1988). Dirr and Heuser (1987) reported that 30 to 60 minutes of sulfuric acid treatment resulted in good germination. A sulfuric acid treatment for 80 minutes and storage for at least 8 months improved germination rates for common laburnum (Laroppe and others 1996). A 2-hour sulfuric acid treatment resulted in 68% (Scotch laburnum) and 106% (Waterer laburnum) germination (Dirr and Heuser 1987). Seeds of Waterer laburnum that were collected when the seedcoat was soft (late July in Boston, Massachusetts) and left “as is” or punctured with a needle produced uniform germination in 5 days (Dirr and Heuser 1987).

Testing prescriptions of the International Seed Testing Association (ISTA 1993) call for mechanical scarification by piercing or by removing a piece of the testa at the cotyledon end and soaking seeds in water for 3 hours before testing them at alternating 20/30 °C for 21 days on germination paper. An alternative method is to scarify seeds by soaking them in concentrated sulfuric acid for 1 hour, washing, and germinating as above (ISTA 1993). Tests of treated seeds can also be done at a constant 20 °C for 14 days, and light is not required (Rudolf 1974). Germination rates averaged about 80% in 7 days, and percentage germination about 86% in more than 12 tests (NBV 1946; Schubert 1955, cited by Rudolf 1974).

Scarified seeds may be sown broadcast or in drills in late spring at a rate of 150 to 200/m² (14 to 19/ft²) for lining-out stock and 100 to 150/m² (9 to 14/ft²) for rootstocks (Macdonald 1986). The seeds are covered with 6 mm (1/4 inch) of soil. Field-planting has been done with 2+0 stock (Rudolf 1974). This species can also be propagated by layering and rooting hardwood cuttings taken during the fall and late winter; cultivars are propagated by grafting or budding onto laburnum seedling rootstocks (Dirr and Heuser 1987; Hartmann and others 1990; LHBH 1976; Macdonald 1986; Whalley and Loach 1981, 1983). Micropropagation of Waterer laburnum ‘Vossii’ has been reported, but plants cultured in vitro have slowed growth as compared to plants multiplied by grafting (Gillis and Debergh 1992).
References

Occurrence, growth habit, and uses. There are about 55 species in the crape-myrtle genus—*Lagerstroemia*. They are indigenous primarily to the Asian and Pacific island tropics but also occur in China, India, Korea, and Australia (Bärner 1962; LHBH 1976). Many are important timber species, producing wood of quality suitable for cabinetry and construction that is also highly resistant to decay and destructive insects (Bärner 1962; Howard 1948). Three species are cultivated in North America, all for their horticultural interest (table 1).

One species of crape-myrtle, *Lagerstroemia indica* L., and its hybrids with *L. fauriei* Koehne—both of which are called crape-myrtle—are used widely in landscape plantings in warmer parts of the continental United States, particularly the South. *Lagerstroemia indica* is indigenous to China, whereas *L. fauriei* was introduced in 1956 by Creech (1958, 1985) from seeds collected on Yakushima Island, Japan. Many cultivars have been named, including a few of strict *L. fauriei* parentage (Dirr 1998; Egolf and Andrick 1978; Raulston and Tripp 1995). Cultivars of crape-myrtles are typically cold hardy to USDA Zone 7, but some cultivars have withstood temperatures of \(-23 °C\) without injury (Egolf 1990b). There have been reports of tropical species, particularly Queen’s crape-myrtle, growing in frost-free portions of the United States corresponding to USDA Zones 10 and 11 (Egolf and Andrick 1978; Everett 1981; Menninger 1962).

Crape-myrtles are deciduous trees or shrubs exhibiting considerable variability in height; they range from 0.9 to 10 m tall, with occasional specimens reaching 14 m (Dirr 1998; Egolf and Andrick 1978). They are observed commonly as upright, multi-stemmed plants, the bottom third to half devoid of leaves, generally exposing very handsome, sinuate trunks (Dirr 1998; Egolf and Andrick 1978). The crown is variably rounded to vase-shaped. Queen’s crape-myrtle may reach 24 m in height in the United States and 30 m in the Asian tropics (Chudnoff 1980).

As a result of their ornamental attributes, crape-myrtles are used extensively as landscape plants. Due to their broad range of heights, they can be observed growing as specimen plants, hedges, mass plantings, or lining streets and alleys (Dirr 1998; Egolf 1981a&b, 1986a&b, 1987a&b, 1990a&b; Egolf and Andrick 1978). Crape-myrtles have also been maintained successfully as herbaceous perennials by annual hard pruning to the ground, and they are treated as herbaceous plants where winter temperatures are low enough to kill aerial portions without injuring the roots (Everett 1981; Huxley 1992). Although widely adaptable, crape-myrtles grow best in full sun and in heavy loam to clay soils with a pH of 5.0 to 6.5 (Egolf 1981a&b, 1986a&b, 1987a&b, 1990a&b; Egolf and Andrick 1978). Crape-myrtles are not grown in the United States for timber use.

Geographic races and hybrids. Various crape-myrtle species hybridize readily. Beginning in 1962, the United States National Arboretum pursued an extensive program of crape-myrtle breeding and selection, under the direction of Egolf (Egolf and Andrick 1978). Between 1981 and 1990, the National Arboretum released 20 cultivars of crape-myrtle, most of them selections of complex crosses between *L. indica* and *L. fauriei* (Egolf 1981a&b, 1986a&b, 1987a&b, 1990a&b). These cultivars combine successfully the superior flowering attributes of *L. indica* with resistance to mildew—*Erysiphe lagerstroemiae* E. West—of *L. fauriei* (Egolf 1981a&b, 1986a&b, 1987a&b, 1990a&b; Mizel and Knox 1993). Several also display the exceptional and colorful, exfoliating bark of *L. fauriei*, as well as outstanding fall foliage color (Dirr 1998; Egolf 1981a&b, 1986a&b, 1987a&b, 1990a&b).

Flowering and fruiting. Spectacular flowering is the trait that most often justifies use of crape-myrtles as landscape plants. The red, white, pink, or purple flowers, each 1.5 to 5.0 cm in diameter, are produced in 12- to 44-cm-long tapered panicles, each comprising 25 to 500 flowers. The flowers are perfect, 6-petaled, and distinctively crinkled. Stamens are numerous, as are ovules (Egolf 1990b; Egolf and Andrick 1978; LHBH 1976). The inflorescences are terminal and prominently displayed at the end of the current year’s growth. Flowering occurs from June to September in the mid-Atlantic states and the Southeast, with some variability between cultivars. Many cultivars have extended flowering periods, lasting up to 3 1/2 months (Dirr 1998; Egolf and Andrick 1978). Fruits are globose, dehiscent, 6-valved capsules, 5 to 15 mm in diameter, that reach maturity in the fall and persist through the winter (figure 1). Each capsule contains 20 or more winged seeds. Seeds are 7 to 11 mm long (figures 2 and 3) (Egolf and Andrick 1978; LHBH 1976).

Collection of fruits, seed extraction, cleaning, and storage. Published information on fruit collection and seed extraction of crape-myrtles is generally lacking, but the capsules should be dried for seed extraction. Dirr and Heuser (1987) placed mature fruits in paper bags for drying, followed by shaking to remove seeds. No information is available currently regarding proper storage conditions to maintain viability, but the seeds appear to be orthodox in storage behavior, indicating that low seed moisture and temperatures would be sufficient for storage. In India, Queen’s crape-myrtle seeds average 150,000 to 175,000/kg (68,000 to 79,400/lb) (Khullar and others 1991).
Pregermination treatments and germination tests. Seeds germinate readily without pretreatment, although stratification (moist prechilling) for 1 month at 4 °C is sometimes advised to synchronize germination (Dirr and Heuser 1987; Raulston and Tripp 1995). There are no officially prescribed test procedures for this genus. However, Babele and Kandya (1986) demonstrated that tetrazolium staining is a reliable and rapid technique for determining seed viability of Lagerstroemia parviflora Rosth.

Nursery practice, and seedling care. Egolf and Andrick (1978) reported that without stratification, seeds sown at 15 °C germinated within 10 days. They recommended that seedlings be transplanted into individual pots shortly after emergence and then fertilized lightly. In a warm greenhouse, such seedlings will make rapid growth, and often bloom the first summer from a December or January sowing. Dirr (1998) reported that germination occurs in 2 to 3 weeks for seeds sown immediately following collection in January. Seedling populations of crape-myrtles, whether of hybrid origin or not, are noted for heterogeneity in height, flower color, floriferousness, and cold hardiness.

At present, commercial propagation of crape-myrtles is primarily by stem cuttings. Softwood, hardwood, or root cuttings have been used successfully (Dirr and Heuser 1987; Egolf 1990b; Egolf and Andrick 1978; Hartmann and others 2002). Micropropagation techniques have also been reported (Yamamoto and others 1994; Zhang and Davies 1986).

Occurrence. The larches—Larix P. Mill.—of the world are usually grouped into 10 species that are widely distributed over much of the mountainous, cooler regions of the Northern Hemisphere (Hora 1981; Krüssmann 1985; Ostenfeld and Larsen 1930; Rehder 1940; Schmidt 1995). Some species dominate at the northern limits of boreal forests and others occur above subalpine forests (Gower and Richards 1990). Seven species are included (table 1)—the others, Master larch (L. mastersiana Rehd. & Wils.), Chinese larch (L. potaninii Batal.), and Himalayan larch (L. griffithiana Carr.)—are rarely planted in the United States. All species (except possibly Himalayan larch) are hardy in the United States (Bailey 1939). However, the seeds should come from a site with comparable conditions, as demonstrated at the Wind River Arboretum in southwestern Washington, where 7 larch species, some with several varieties, and 1 hybrid were planted from 1913 to 1939 (Silen and Olson 1992). European larches there are doing better than Asian species in this warm, moist Washington state climate. The native western larch specimens from more continental climates with lower humidity are doing poorly. In 1992, a larch arboretum containing all species, several varieties, and 3 hybrids of larch was established at Hungry Horse, Montana, within the natural range of western larch (Shearer and others 1995).

Growth habit. Larix is one of the few conifer genera with deciduous needles. The trees are valued for their light green hues in the spring and shades of yellow to gold in the autumn.

fall. Branching is usually pyramidal with spreading branches (Hora 1981). Maximum height for the 10 species ranges widely, influenced by elevation and site conditions. Subalpine and Chinese larches often grow at or near timberline and mature trees may reach only 7 to 13 m in height (Kruismann 1985). The tallest known subalpine larch, as reported by Arno and Habeck (1972), grows on a protected, favorable site and reached 46 m. Western larch, tallest of the world’s larch species, can reach about 61 m (Schmidt and others 1976; Schmidt and Sherar 1990).

Use. Of the 3 American species, tamarack and western larch are used for reforestation. Because of its rot resistance, larch wood is especially valuable for posts, transmission poles, railroad ties, and mine props. Most larches are now recognized as important for timber production, habitat or food for wildlife, watershed protection, environmental forestry, and also for ornamental purposes (Rudolf 1974). Venetian turpentine can be obtained by tapping larches; a water-soluble trisaccharide sugar melecitose is extracted from wood chips (Dallimore and Jackson 1967; Hora 1981). Probably because of this high sugar content, black bears—*Ursus americanus cinnamonum*—often seek out vigorous young pole-size western larch in late spring and feed on the inner bark and cambium, usually on the lower 1 to 2 m of the trees (Schmidt and Gourley 1992). Often the trees are girdled and die; partially girdled trees frequently produce large cone crops following damage (Sherer and Schmidt 1987).

Genetics. Larch species vary widely in growth rates, cold hardiness, form, pest resistance, and other characteristics. This variability is often under strong genetic control and genetic gain is expected through tree improvement efforts (Eyestenisson and Greenwood 1995). Winter hardiness, change in foliage color, and cessation of height growth of Japanese larch were correlated with latitude of provenance origin, but date of bud flush was not (Toda and Lee 1989). Ait.) in another Wisconsin study (Lee and Schabel 1984) and in Wisconsin (Riemenschneider and Nienstaedt 1983); Dunkeld larch showed best growth in both studies. Conversely, low genetic variation occurs among populations of western larch for growth, phenology, and cold hardiness (Rehfelt 1982) compared with other Rocky Mountain conifers. Rehfelt (1983) identified an 11% variation associated with the elevation of the seed source and recommended that seedlots not be transferred more than ± 29 m or ± 2 contour bands. Based on genetic variation in allozymes of western larch seeds, Fins and Seeb (1986) cautioned transferring seeds from eastern Washington to north Idaho and recommended that seedlots for planting should include seeds from a diversity of locations within an area. Hall (1985) concluded that yields of cones and seeds from interspecific and intraspecific crosses and open-pollinated seeds of European larch were reduced in hybrid crosses compared to non-hybrid crosses. Wide variation in yield suggests that both genetic and environmental factors are important in controlling yield of seeds.

Hybrids. Larches hybridize readily (Rudolf 1974; Lewandowski and others 1994; Young and Young 1992), and geographic isolation is a major factor for lack of hybridization. Natural hybrids of western and subalpine larches occur where their ranges overlap (Carlson and Blake 1969; Carlson and others 1990). Seeds from natural hybrid trees closely resemble those of western larch (Carlson and Theroux 1993). Reciprocal cross pollinations between western and subalpine larches were successful, and germination of seeds from these crosses was higher than that of seeds from either parent (Carlson 1994).

*L. kaempferi* × *decidua*, known as *L. × eurolepis* A. Henry and commonly called Dunkeld larch, originated about 1900. It has been planted extensively in northwestern Europe and to a lesser extent in the eastern United States and Canada because it combines desirable characteristics of both parent species and grows faster than either (Elison 1942; MacGillivray 1969). *L. kaempferi* × *sibirica*, known as *L. × marschallianus* Coaz, was originated in 1901. *L. laricina* × *decidua*, known as *L. pendula* Salisb. or weeping larch, was originated before 1800 (Rehder 1940). Many other larch hybrids are known. Several larch species and hybrids were tested as potential short-rotation fiber crops for the Northeast and the Great Lakes region (Einspahr and others 1984) and in Wisconsin (Riemenschneider and Nienstaedt 1983); Dunkeld larch showed best growth in both studies. Seeds from a single provenance of Japanese larch and 6 provenances of European larch had, after 5 years, 3 times the growth potential of seeds from native red pine (*Pinus resinosa* Ait.) in another Wisconsin study (Lee and Schabel 1989).
Geographic races. Geographic races have developed in many widely distributed larch species, and these often exhibit marked differences in growth rates and other characteristics (Rudolf 1974). The European larch includes at least 5 geographic races (often considered to be subspecies or varieties) that roughly coincide with major distributional groups of the species (Debazac 1964; McComb 1955):

- Alpine, in south central Europe
- Sudeten, principally in Czechoslovakia
- Tatra, in Czechoslovakia and Poland
- Polish, principally in Silesia
- Romanian (several small outliers)

The races differ in seed size and viability, survival after planting, growth rate, phenology, form, and resistance to insects and disease (Dallimore and Jackson 1967; McComb 1955; Rudolf 1974). The races respond differently in different localities, but in the northeastern United States and Canada, the Polish and Sudeten races grow most rapidly and are recommended for planting there although they do not always have the best form (Hunt 1932; MacGillivray 1969). Sindicelar reported (1987) that in Czechoslovakia, seedlings of Dunkeld larch and L. decidua x gmelini grew better on sites with high levels of pollution than did European larch seedlings. Sindicelar (1982) recommended that seed orchards of European larch contain many clones in order to prevent excessive propagation of a few fertile clones. A Scots race mentioned in older references probably developed in Scotland from plants of Sudeten origin (Rudolf 1974).

European seed sources perform similarly in northeastern United States as in Great Britain, Germany, and Italy (Genys 1960).

Some varieties of Dahurian larch that are confined to definite areas appear to be geographic races (Debazac 1964). These include the following varieties:

- japonica (Maxim. ex Regel) Pilg.
- principis-rupprechti (Mayr) Pilg.
- olgensis (A. Henry) Ostenf. & Syrach., known as Olga Bay larch (Rehder 1940)

In China, L. principis-rupprechti and Olga Bay and Chinese larches are recognized as distinct species rather than geographic races of Dahurian larch (Chinese Academy of Sciences 1978). Tests in Finland showed marked differences in survival, growth rate, cold hardiness, and susceptibility to insect attack between trees from Korean and Sakhalin seed sources (Kalâla 1937). A limited trial in North Dakota was unsuccessful (Cunningham 1972). Trees of Olga Bay larch seem suitable for planting in north central United States and adjacent Canada.

Because of the extensive natural range of tamarack, geographic races probably exist. Studies by Cheliak and others (1988); Farmer and others (1993), and Park and Fowler (1987) reported differences in growth, such as total height based on latitude and late-season elongation. Two-year-old seedlings of tamarack grown in Minnesota from seeds from several origins showed significant differences in total height and a tendency for bud set to occur earliest in seedlings from northern sources (Pauley 1965).

Japanese larch is native to a 365-km² area in the mountains of central Honshu, where it grows in scattered stands at elevations of 900 to 2,800 m (Asakawa and others 1981). Despite this small native range, test plantings of Japanese larch in several parts of the United States and eastern Canada, Japan, China, Great Britain, and Germany have shown significant differences among seed sources in tree height, survival, terminal bud set on leader, number of branchlets, insect resistance, winter and spring cold damage, and susceptibility to sulfur fumes (Hattemer 1968; Heimburger 1970; Lester 1965; MacGillivray 1969; Wright 1965). Progeny of seeds from diverse sources respond differently to particular environments, so that no general recommendations can be made as to the best races for specific localities. However, seeds from sources in the northern part and the higher elevations of Honshu have produced progeny with earlier hardening off and less early frost damage that have seeds collected from further south and at lower elevations (Hattemer 1968; Heimburger 1970; Lester 1965; Wright 1965).

Siberian larch stock grown from seeds from the Altai region seem to be less cold hardy than stock grown from seeds from other parts of the range (Tkachenko and others 1939). Limited trials in North Dakota suggest that this species could be used as the tallest member of a multiple-row shelterbelt (Cunningham 1972).

Flowering. Male and female flowers of the larches are borne separately on the same tree. Cones are usually scattered throughout the non-shaded crown with seed cones more frequent higher in the crown and pollen cones more frequent lower in the crown (Eis and Craigdallie 1983), but there usually is considerable overlap. They occur randomly with the leaves on the sides of twigs or branches and usually open a few days before needle elongation. The male flowers are solitary, yellow, globose-to-oblong bodies that bear wingless pollen. The female flowers are small, usually short-stalked, erect, red or greenish cones that ripen the first year.
The seed cones and pollen cones usually are differentiated in terminal positions on short-shoot axes that completed at least 1 cycle of annual growth (Krittsman 1985; Owens and Molder 1979a). However, the seed and pollen cone buds of tamarack (Powell and others 1984) and Japanese larch (Powell and Hancox 1990) can differentiate laterally on long shoots the year they elongate. Furthermore, as tamarack plantations go from 5, 6, to 7 years of age, the number of trees bearing seed and pollen cones and the number of cones per tree increased each year (Tosh and Powell 1991). Top-grafting buds of 2-, 5-, 9-, 45-, and 59-year-old Japanese larch on 17-year-old trees shortened the time to produce female and male strobili by about 5 years over untreated controls (Hamaya and others 1989). Loffler (1976) found that yield of European larch seeds in seed orchards usually increased with grafted age and in comparison to the natural forest, the cones provided more and larger seeds of better quality. Ten years after planting in a common garden, western larch cone production was twice as great for trees grafted with mature scions as for seedlings and five times greater than for rooted cuttings (Fins and Reedy 1992). The number of seed and pollen cones increased on 30- to 32-year-old western larch as average spacing expanded from 2 m to 3 m and wider (Shearer and Schmidt 1987). The average number of cones produced per tree during a good cone crop increased 27 times as the diameter classes increased from 10 to 15 cm to 30 to 36 cm, a reflection of the greater crown volume (Shearer 1986). Xu (1992) found similar relationships for Dahurian larch in China.

There was no relationship of the number of cone scales of Olga Bay larch or their color, shape, size, or structure to site characteristics, developmental stage of trees, or other biological factors (Suo 1982). Developing larch cones range in color from red to green with a range of intermediate shades. Raevshik (1979) reported that red- and green-coned forms of Dahurian larch produced better quality seeds than did rosy-coned forms. Western larch cones are red, green, and brown in color, but no differences were detected in seed quality by color (Shearer 1977). Ripe cones become brownish and have woody scales, each of which bears 2 seeds at the base (Dallimore and Jackson 1967; Rehder 1940). The seed has a crustaceous, light-brown outer coat; a membranaceous, pale chestnut-brown, lustrous inner coat; a light-colored female gametophyte; and a well-developed embryo (figures 1 and 2) (Dallimore and Jackson 1967; Rehder 1940). Occasionally, atypical cones are found on larches. Tosh and Powell (1986) identified and studied proliferated and bisporangiate cones on tamarack planted 5 or 6 years earlier.

A 10-year phenological record of western larch in the Northern Rocky Mountains showed a wide range in time of bud-burst, pollination, and cone opening (Schmidt and Lotan 1980). A 21-year phenological study of subalpine larch showed that spring temperature, not photoperiod, was a chief factor that determined bud-burst date (Worrall 1993). Morphological studies increased our understanding of characteristics of cones and seeds of tamarack (O’Reilly and
European and Dunkeld larches after controlled crossings age has been used to protect pollinated female strobili of an expensive electrical resistance device that prevents frost damage. An insecticide that prevents frost killed a high proportion of European larch cones. An insecticide was effective in promoting strobilus production in grafts on 10-year-old Japanese larch. Frost may completely killed the cone crop of Olga Bay larch growing in a seed orchard of European larch. In late May 1968, frost described spring frost damage to 14 grafted Polish clones in a seed orchard of western larch (de Groot and others 1994). Lewandowski and Kosinski (1989) often limits the number of developing cones that mature and germinate on the nucellus, and embryo degeneration as major factors reducing seed yields of tamarack and European, Japanese, and Siberian larches in the upper peninsula of Michigan, although the previously mentioned 5 factors also caused seed loss. Factors contributing to empty seeds in European larch included lack of pollination, disturbances during megasporogenesis, failure of pollen to reach and germinate on the nucellus, and embryo degeneration (Kosinski 1986, 1989).

Throughout much of the range of western larch, frost often limits the number of developing cones that mature (Shearer 1990). Lewandowski and Kosinski (1989) described spring frost damage to 14 grafted Polish clones in a seed orchard of European larch. In late May 1968, frost completely killed the cone crop of Olga Bay larch growing above 1,000 m in northeastern China (Suo 1982). Frost may also limit cone production of subalpine larch most years (Arno 1990). Loffler (1976) found that late spring frost killed a high proportion of European larch cones. An inexpensive electrical resistance device that prevents frost damage has been used to protect pollinated female strobili of European and Dunkeld larches after controlled crossings (Ferrand 1988). Indoor (potted) orchards are used to produce western larch seeds and to control the environmental conditions that often limit cone production in natural or planted stands (Remington 1995). Ross and others (1985) suggested many other advantages. Flowering of tamarack was promoted on potted, indoor, and field-grown grafts by foliar sprays of gibberellin (GA_{3}) and root pruning (Eysteinsson and Greenwood 1990). Seed cone flowering decreased per centimeter of branch length as ortet age increased from 1 to 74 years (Eysteinsson and Greenwood 1993). Ross (1991) determined that response to combinations of stem girdles and GA_{3} injections on 17-year-old western larch varied greatly in flowering response. Only the effects of girdling (not GA_{3}) were effective in promoting strobilus production in grafts on 10-year-old Japanese larch (Katsuta and others 1981).

**Damage.** During poor cone crop years with some larch species, many of the seeds are destroyed by weevils (Radolf 1974). Several insects limit western larch cone and seed production. The majorcone feeding insects are the larch cone maggots (*Strobilomyia laricis* Michelsen), western spruce budworm (*Choristoneura occidentalis* Freeman), a woolly adelgid (*Adelges viridis* Ratzeburg), and cone scale midges (*Russeiliea sp.*). A woolly adelgid larvae caused damage (Amirault 1989; Amirault and Brown 1986). A woolly adelgid *Adelges viridis* *Ratzeburg*) larvae cause damage (Amirault 1989; Amirault and Brown 1986). Similarly, the eastern spruce budworm (*Choristoneura fumiferana* Clem.) greatly decreases cone and seed production of tamarack (Hall 1981). The eastern spruce budworm and cone fly (*Lasiomma viarium* Hackett) larvae caused most damage to seeds of tamarack in 1982 and 1983 in New Brunswick and Maine, whereas other insects caused lesser damage (Amirault 1989; Amirault and Brown 1986). A recent review of insects that may influence larch cones and seeds in Canadian seed orchards listed 19 species in 4 families: 1 insect species for subalpine larch, 17 species within 4 families for tamarack, and 4 species within 3 families for western larch (de Groot and others 1994). In British Columbia, neither tamarack nor western larch have major insect pests (Eremko and others 1989).
Atmospheric fluorides can reduce the size of seeds, percentage germination, numbers of seeds per cone, and numbers of cones per tree. Reproductive failure and mortality of tamarack in Newfoundland have resulted in their replacement by more tolerant species (Sidhu and Staniforth 1986).

**Micropropagation and genetic engineering.** Micropropagation techniques can supplement reliance on larch seeds for a broad range of tree improvement and regeneration needs. Karnosky (1992) suggests biotechnology can help produce genetically superior larch by (1) mass propagation, (2) disease screening, and (3) transfer of genetic information through genetic engineering techniques. Organogenesis from young and mature larch callus tissues is reported (Bonga 1984; Chapula 1989). Lelu and others (1993) developed somatic embryogenesis techniques for several species and hybrids of larch. Full-sib immature zygotic embryos were produced from induction of embryonal masses for European and Dunkeld larches and Larix × leptoeuropae (Lelu and others 1994a). Thompson and von Aderkas (1992) successfully regenerated western larch from immature embryos. Protoplasts of Dunkeld larch can be effectively isolated from embryonal mass and cultured to produce somatic plantlets (Charest and Klimaszewska 1994). Further, Lelu and others (1995) showed that the number of mature somatic embryos of Larix × leptoeuropae produced per gram (fresh weight) of embryonal mass was influenced by embryogenic line, sucrose concentration, and abscisic acid concentration. No universal maturation medium was recommended because of the interactive effects of these 3 factors. High plantlet survival was achieved in the greenhouse through either of 2 acclimatization methods (Lelu and others 1994c). In gymnosperms, gene transfer was first accomplished in European larch; transfer was mediated by Agrobacterium rhizogenes and subsequent regeneration of the transgenic plants (Huang and others 1991). Shin and others (1994a & b) reported that transgenic European larch plants were produced that use Agrobacterium-mediated single gene transfer to promote insect (Bt toxin gene) and herbicide (aroA gene) resistance.

**Collection of cones.** Larch cones should be collected as soon as they ripen; different species ripen at various times from August to December (table 2). Larch cones are picked from trees in forests, seed production areas, seed orchards, and potted tree collections or they can be gathered from felled trees, slash, or squirrel caches. In Tyrol, European larch seed were picked from the snow by hand; they can also be gathered in late winter from canvas spread on the ground before the trees were shaken to release the seeds (Rudolf 1974). In most species, ripe cones are brown. Tests show that seedcoats are hard and that female gametophytes are firm. Often seeds mature earlier than expected and the period for cone collection for tamarack (Smith 1981) and western larch (Shearer 1997) can be expanded. Cones of Siberian larch should be harvested when needles start to turn yellow to assure high-quality seeds (Lobanov 1985). Data on height, seed-bearing age, seed crop frequency, and ripeness criteria are listed in tables 3 and 4.

**Extraction of seeds.** Freshly collected cones should be spread out in thin layers to dry in the sun or in well-ventilated cone sheds. The cones can be opened by solar heat, by heating in a cone kiln or room, or by tearing them apart mechanically (Rudolf 1974; Rudolf and others 1939). Recommended kiln schedules are 8 hours at 49 °C for tamarack and 7 to 9 hours at 43 °C for western larch (Rudolf 1974). After opening, cones should be run through a shaker to remove the seeds. Sometimes equipment must be modified to extract larch seeds (Saralidze and Saralidze 1976). Seeds can then be de-winged by a de-winging machine, by treadling in a grain sack, or by hand-rubbing. The integument, which attaches the wing to the seed, is difficult to remove in normal processing without damage (Edwards 1987). Finally,
seeds should be cleaned with a blower or fanning mill. A mechanical macerator is routinely used for processing tamarack cones and for de-winging larch seeds (Wang 1995).

Seed yields for 5 species are listed in table 5 and the number of cleaned seeds for 7 species is shown in table 6. Simak (1973) reported that, although European larch seeds can be upgraded by flotation in 80% to absolute alcohol for 5 to 15 minutes with a loss of less than 5% germinability, he recommended using water as an optimal liquid for flotation. In addition, Simak (1966) also reported that a seed sample of Himalayan larch had 28% filled seeds and weighed 4.68 g/1,000 seeds (214,000 seeds/kg). Cooling cones and seeds of western larch so that the resin forms globules and becomes less sticky facilitates extraction and cleaning (Zensen 1980).

Purity of larch seedlots has ranged from 84 to 94%, but filled seed values have consistently been low at 50 to 70% (Rudolf 1974). The low percentage of filled seed may be attributed to the development of many unfertilized seeds and to woody or resin deposits in them. The woody tissue or resin hinders their removal in the cleaning process (Edwards 1987; Rudolf 1974). In lots of tamarack seeds from Ontario, 50% were sound; most of the unsound seeds had incompletely developed embryos and endosperm (Farmer and Reinholt 1986). Hall and Brown (1977) found similar conditions among seeds of European and Japanese larches and their hybrids. Seeds of western larch also have a high proportion of embryo failures (Owens and Molder 1979b). Use of X-radiography was recommended to evaluate the quality of tamarack seeds because flotation in 95% ethanol killed 52% of germinable seeds (Eavy and Houseweart 1987). A purity of 80% and a viability (germinative capacity) of 20% were recommended in 1966 as minimum standards for western larch (WFTSC 1966). Current standards for tree seeds to be certified under OECD Certification in Ontario require a minimum of 95% purity for tree seeds, resulting in an average germinability of 75 to 80% at 15 years for tamarack (Wang 1995).

Storage of seeds. Because larch seeds can be stored for long periods at seed moisture contents of 5 to 10% in sub-freezing temperatures, Bonner (1990) classifies them as “true orthodox” seeds. Gordon (1992) found that larch seeds can be stored at 6 to 8% moisture content at 1 to 3 °C for 25 years with little or no loss of germination quality. European

larch seeds keep well for a year or two if stored in the cones (Rudolf 1974). Tamarack seeds store very well at 2 °C for 10 years (Wang 1982). Details on seed storage for 6 species are shown in table 7. There was no significant difference in viability of European larch seeds stored at 0 °C or in liquid nitrogen (−196 °C) for 1 to 6 days (Ahuja 1986). European larch seeds (Sudeten source) collected in 1956 and stored at 9% moisture content showed little decrease in germination, if any at all, over a 12-year period (Hill 1976).

Pregermination treatments. Seeds of most larch species germinate without pretreatment, but stratification in moist medium usually hastens the germination process. Subalpine larch has a thick seedcoat and seeds rarely germinate after 30 days of stratification on moist blotting paper, but Carlson (1994) and Shearer and Carlson (1993) obtained good germination by stratifying seeds for 30 days in a slightly acid, sphagnum-based soil. Germination of subalpine larch also improved after seeds were soaked in 1% hydrogen peroxide for periods of 6 to 24 hours (Shearer 1961). Other pre-germination treatments used for western larch seeds include soaking them in water for 18 days at 1 °C or in USP 3% hydrogen peroxide (H₂O₂) for 12 to 24 hours.

hours (Schmidt 1962; Shearer and Halvorson 1967). Unstratified seeds of tamarack from Ontario provenances germinated completely in light at a range in incubation temperatures but only stratified seeds could be germinated in the dark at lower temperatures (Farmer and Reinholt 1986). Brown (1982) reported similar results for tamarack seeds from Alaska. Wang (1995) reported pregermination results for 4 species of larch:

- Daurian larch seeds did not require cold stratification or prechilling for maximum germination, but seeds stratified for 3 weeks germinated more uniformly with or without light. Non-stratified seeds germinated best with a 16-hour photoperiod than in darkness or with an 8-hour photoperiod.
- Japanese larch seeds that were stratified for 3 weeks showed significantly more germination than those that were not stratified.
- European larch seeds did not require stratification for maximum germination.
- Tamarack seeds did not require stratification for maximum germination but their germination rate was much improved.

One or two cycles of cold stratification followed by dehydration improved percentage and speed of germination of a variety of Daurian larch (L. gmelinii var. principis-rupprechtii Mayr) (Chang and others 1991). Kuznetsova (1978) found that germination of Daurian larch seeds was enhanced by storing moist seeds in cloth bags on frozen soil under snow.

*Viability of 5% retained after 16 years of storage.

Germination. Germination of larch seeds is epigeal (figure 3) and may be tested in germinators or sand flats. Both the Association of Official Seed Analysts (AOSA 1993) and the International Seed Testing Association (ISTA 1993) recommend the same germination test procedures: germination on top of moist blotters or other paper products for 21 days at temperatures alternating diurnally from 20 °C during a 16-hour dark period to 30 °C during an 8-hour light period. For western larch, duplicate tests of untreated seeds and seeds that are stratified for 21 days at 3 to 5 °C are recommended. An attainable standard for purity and viability for western larch seeds is 90 and 60%, respectively (Stein and others 1986). Further, they recommend that test seeds be germinated either on the top of blotters or in petri dishes at 20 to 30 °C for 3 weeks in light. Li and others (1994) showed that light may reduce germination of stratified seeds and had no effect on unstratified seeds of western larch. Sorensen (1990) recommended short stratification periods for germination in a warm greenhouse but longer ones will improve uniformity of emergence. Methods used and average results for 6 larch species are summarized in table 8. Less-used techniques to increase germination of Siberian larch include (a) presoaking seeds and subjecting them to laser radiation (Dobrin and others 1983) and (b) subjecting seeds to UHF electromagnetic field exposure (Golyadkin and others 1972).

* Only fall-sown beds should be mulched.
† Only seeds that have been stratified in moist sand or vermiculite at 0 to 9.5 °C for 14 or 42 days.
Nursery practice. Larch seeds should be sow unstratified in the fall or stratified in the spring and covered with 3 mm (0.13 in) of sand or nursery soil. Fall-sown beds should be covered with burlap or mulched with straw or litter over the first winter; the mulch can be removed before germination commences in the spring (Rudolf 1974). Harbi (1989) determined that soaking European larch seeds in water for 24 hours followed by drying, also for 24 hours, permitted mechanized sowing and resulted in high germination. Some details as to nursery practice for 5 species are listed in table 9. Larches have few enemies in the nursery, although a species of the fungus Larch sawfly, may damage western larch plantations in the seedbed (Rudolf 1974).

The weight of Japanese larch seeds had some effect on initial size of seedlings, but most variation was attributed to differences in the rate of germination (Logan and Pollard 1981).

Larches grow in almost any kind of soil, including clay and limestone, but they develop best when grown in the open on somewhat moist, but well-drained soils. Proper selection of planting sites and seed sources reduce the risks associated with growing non-native larch (Robbins 1985). Tamarack and introduced larches growing on appropriate sites produce high fiber yields on rotations that are economically attractive (Carter and Selin 1987). The larch casebearer (Coleophora lariellae (Hubner)) and the western spruce budworm (Choristoneura occidentalis Freeman) may cause serious damage to western larch plantations in the West (Fellin and Schmidt 1967) and the larch sawfly (Pristiphora erichsoni (Hartig)) may damage all species of larch in many areas.

*Larrea tridentata* (Sessé & Moc. ex DC.) Coville
creosotebush

Richard T. Busing

Dr. Busing is an ecologist at the USDI Geological Survey, Corvallis, Oregon

**Synonyms.** *Larrea tridentata* (DC.) Cov.

**Other common names.** greasewood, gobernadora, hediondilla.

**Growth habit and occurrence.** Creosotebush—*Larrea tridentata* (Sessé & Moc. ex DC.) Coville—is an evergreen shrub native to the arid subtropical regions of the southwestern United States, Mexico, Argentina, and Chile (Benson and Darrow 1945). Whether the North American species *L. tridentata* is distinct from the South American species *L. divaricata* Cav. has been unclear (Benson and Darrow 1945), but most recent authors recognize *L. tridentata* as a separate species. It is the dominant shrub in all 3 warm deserts of the United States: the Mojave, Sonoran, and Chihuahuan Deserts (Barbour and others 1980). Although creosotebush can grow on a variety of substrates, it is most abundant on calcareous soils (Musick 1978). Stands vary in density and stature, depending on the aridity of the site (Woodell and others 1980). Under very low rainfall, shrubs are smaller and more widely spaced than those in stands under more mesic conditions. Morphological and physiological adaptations of the genus *Larrea* to growth under xeric conditions are well studied (Barbour and others 1974, 1977). Despite dominance of the species in xeric sites, the emergence and growth of seedlings is favored by mesic conditions. Moisture, neutral pH, low salinity, and moderate temperatures are conducive to successful germination and seedling establishment (Barbour and others 1977).

**Use.** Creosotebush is not browsed by livestock. Although an edible livestock feed has been made from creosotebush and a valuable antioxidant has been extracted from the shrub (Duisberg 1952), no economically feasible program for gathering and using large amounts of creosotebush has been developed. Creosotebush, like other common plants with peculiar odor or taste, has been used in traditional medicine to cure various ills (Benson and Darrow 1945). In arid and semiarid parts of the Southwest, creosotebush is used for landscaping and reclamation of disturbed lands (Day and Ludeke 1980; Graves and others 1978; Williams and others 1974).

**Flowering and fruiting.** Creosotebush has perfect flowers. It blooms most profusely in the spring but may flower from time to time throughout the year (Kearney and Peebles 1951; Valentine and Gerard 1968). The fruit is a densely white, villous, 5-celled capsule (Kearney and Peebles 1951). When fruits are cast, they separate into individual carpels, each normally containing 1 seed (figures 1 and 2) (Martin 1969). Carpels fill under natural conditions averages 35% (range 12 to 62%) (Valentine and Gerard 1968). Plants may fruit sparingly at 4 to 6 years of age and reach full fruiting maturity at 8 to 13 years (Martin 1974). Annual production ranges from 39 to 278 fruits/100 g (11 to 79/oz) of branch or from 119 to 1,714 fruits/plant (Valentine and Gerard 1968).

**Collection, extraction, and storage.** Ripe fruits may be collected from the shrub in the late spring or early summer. Fumigation or dusting fruits with insecticide is advisable to prevent insect damage. Clean seeds, extracted from the carpels, are small—there are about 374,800/kg (170,000/lb)—and are not usually available on the market (Knipe and Herbel 1966; Martin 1969). Viability of seeds in carpels declined little after 2 to 4 years in dry storage at room temperatures, and some 7- to 8-year-old lots germinated well (Barbour and others 1977; Valentine and Gerard 1968). This information strongly suggests that the seeds are orthodox in storage behavior and should store well for many years at low temperatures and moisture contents.

**Figure 1**—*Larrea tridentata*, creosotebush: single carpel.
average percentage germination (93%) over a range of 10 to 60 °C. Yet, exposing seeds to warm temperatures (over 37 °C) has been found to reduce germination, and continuous exposure to cold temperatures prior to sowing is desirable (Barbour 1968). Storage in partially sealed plastic bags with activated carbon for 30 days at 2 °C is recommended for high percentage germination (Graves and others 1975).

Germination. There are no official testing prescriptions for creosotebush. In one series of tests, germination of unscarified seeds (computed on filled carpel basis) in carpels at 17 °C ranged from 55 to 90% (average 74%) (Valentine and Gerard 1968). Carpels were dusted with fungicide and placed on moist blotter paper in petri dishes in humidified germinators (Valentine and Gerard 1968). Fungicide treatments may delay and reduce germination, however (Tipton 1985). Conditions conducive to germination include darkness (Barbour 1968; Tipton 1985), high moisture with wetting and drying cycles (Barbour 1968; McGee and Marshall 1993), temperatures near 23 °C, low salinity, and near-zero osmotic pressure (Barbour 1968).

Seedling care. Seedling survival is very low in natural populations (Ackerman 1979), and large-scale seedling establishment is thought to be rare (Barbour 1968). Heavy rains in late summer increase seedling germination and survival (Ackerman 1979; Boyd and Brum 1983). Under laboratory conditions, maximum root growth occurred at 29 °C in a medium that was slightly acidic, non-saline, and near-zero osmotic pressure (Barbour 1968). Seedlings grown in acidic media are highly susceptible to phosphorus toxicity (Musick 1978).

Other common names. trapper’s-tea, trapper’s tea.

Growth habit, occurrence and use. The genus *Ledum*—Labrador-tea—comprises 3 evergreen shrubs with a wide distribution (table 1). Plants range from 0.3 to 0.8 m tall and are much-branched. The leaves are leathery, lance-shaped, and hairy on the lower surface and have a characteristic spicy fragrance. Labrador-tea produces seeds vigorously; in its natural environment it can reproduce either from seeds (McGraw and Shaver 1982) or vegetatively (Sumner 1964). The below-ground system develops as result of layering by the above-ground shoots, and as much as 5 times more biomass has been documented below-ground than above, with clones covering 5 to 10 m² (Calmes and Zasada 1982). Marsh Labrador-tea is an alternate host for spruce needle rust—*Chrysomyxa ledicola* Legerh. (Ziller 1974).

Sumner (1964) gives a detailed description of Labrador-tea morphology in interior Alaska. Leaves of marsh Labrador-tea can be boiled to make an aromatic tea; excessive doses can cause drowsiness or intestinal disturbance. Labrador-tea produces a sesquiterpene, germacrone, that makes it highly unpalatable to snowshoe hares (Reichardt and others 1990). Western Labrador-tea contains toxic alkaloids known to be poisonous to livestock (MacKinnon and others 1992).

Flowering and fruiting. Flower buds are initiated in the summer months at the tips of new shoots. They overwinter and flower the following spring, in late May and early June (Reader 1982). Flowers are white, with protruding stamens; they occur in numerous umbel-like clusters. Fruits occur as drooping clusters of dry capsules (figure 1). A large number of seeds are produced per flower. Sumner (1964) found a range of 34 to 181 seeds per fruit in her study of marsh Labrador-tea in interior Alaska. Extensive flowering is common. Seeds are small (bog Labrador-tea, 1.8 to 3.0 mm by 0.2 to 0.3 mm; marsh Labrador-tea, 1.4 to 2.0 mm by 0.2 to 0.3 mm) (Karlin and Bliss 1983). Seedcoats are golden and translucent, with a loose, elongated testa that aids wind dispersal (Densmore 1997). Calmes and Zasada (1982) found that only 45% of bog Labrador-tea seeds were filled.

Extraction, cleaning, and storage of seeds. Seed capsules open as they dry, readily releasing seeds. Empty capsules can be separated from seed with a fine-mesh sieve. Most seed viability is lost within 1 year of collection. When seeds were stored for 22 months at 4 °C, germination dropped from 58 to 16% (Karlin and Bliss 1983).

Pre-germination treatments. Labrador-tea does not require cold stratification for germination, but most data suggest that stratification improves germination. In a study of marsh Labrador-tea, seeds exhibited shallow dormancy (Calmes and Zasada 1982); 30 days of cold stratification is necessary for germination.
increased the rate and percentage of germination. Densmore (1997) achieved 100% germination of marsh Labrador-tea at 20 °C and with 20 hour day-length following cold stratification. In another study, marsh Labrador-tea germinated best without any stratification (Karlin and Bliss 1983).

**Germination tests.** Seeds can be sprinkled on the surface of a moist substrate and covered with clear plastic film. Light is required for germination (Calmes and Zasada 1982; Karlin and Bliss 1983); germination is enhanced with longer day-lengths (Densmore 1997). In addition to light, optimal germination conditions include a continually moist, somewhat acidic substrate (pH 5.5) and mean daily temperatures ≥ 17 °C (Karlin and Bliss 1983). Treating seeds with gibberellic acid greatly increased germination under a variety of environmental conditions (Junttila 1972).

**Nursery practice.** Marsh Labrador-tea has been successfully propagated from seeds for horticultural purposes. The seeds should be sown thinly in boxes of pure, finely sifted peat moss, and then covered with a fine dusting of peat moss (Sheat 1948). Cuttings taken from mature plants in mid-December rooted well (Dirr and Heuser 1987), but below-ground stem cuttings produced few new shoots (Calmes and Zasada 1982). Half-mature side shoots can be pulled off and rooted in a mixture of peat moss, loam, and sand (Sheat 1948).

**Seedling care.** Labrador-tea seedlings are fragile and slow-growing. After 4 months of growth in a greenhouse, seedlings of bog Labrador-tea were only a few millimeters tall (Sumner 1964). Though seeds can germinate in water-saturated substrates, seedling survival and establishment are enhanced with better drainage.

Growth habit, occurrence, and use. The genus *Lespedeza* includes about 140 species of shrubs, sub-shrubs, and herbs (Hensen 1957). Most species are native to the temperate regions of eastern Asia and only about 11 species are considered native to North America (Clewell 1966). All native species are herbaceous; however, several species of shrub lespedeza have been introduced into the United States (table 1). The non-native shrub lespedezas tend to have herbaceous stems with woody bases. All species listed in table 1 are planted for conservation and management purposes (Kelsey and Dayton 1942; Stranbaugh and Core 1964). Both shrub and Thunberg lespedezas are commonly referenced in the floristic literature (Gleason and Cronquist 1991). Leafy lespedeza, a less frequently referenced species, is noted by some to occur in the central-eastern United States (Clewell 1966; Isely 1990; Kartesz 1994). Although the name *L. japonica* has been used since the 1930s, many of the *L. japonica* materials have been re-identified as *L. thunbergii* (Vogel 1974). Classification of these shrubs is difficult and confused because of variation resulting from interspecific hybridization (Clewell 1966). Shrub lespedeza is the most common and widely planted shrub in the genus in the United States (Davison 1954; Vogel 1974).

Lespedeza shrubs are adapted primarily to the southeastern two-thirds of the United States, except for southern Florida (Clewell 1966; Davison 1954). They are planted mainly for wildlife food and cover (Owsley and Surrency 1989) and for erosion control (Gabrielson and others 1982; USDA SCS 1980). Soil enrichment by nitrogen-fixing symbionts is also a potential benefit (Allen and Allen 1981). The seeds are preferred quail food (Clewell 1966; Davison 1954; Vogel 1974). Some plantings have been made for ornamental purposes (Clewell 1966; Crider 1952). Grown to maturity, plants of shrub lespedeza may reach a height of 3 m but more commonly 1.2 to 2.4 m (Crider 1952; Davison 1954; Vogel 1974). In management for seed production, stems of some shrub lespedezas must be cut back to the ground (Davison 1954; Vogel 1974).

**Superior strains.** Superior strains of shrub lespedeza have been selected and developed mostly at the plant material centers of the USDA Natural Resources Conservation Service (formerly the Soil Conservation Service) in the East and Southeast (Vogel 1974). Strains 100 and 101 of shrub lespedeza were developed for their greater production of seed and persistence of fruits on the plants after ripening (Davison 1954). *L. bicolor* ‘Natob’ matures seeds much earlier and is more winter-hardy than any other strain of shrub lespedeza grown in the United States. Thus, it can be grown farther north than other shrub lespedezas (Clewell 1966). A selection of Thunberg lespedeza called VA-70 (USDA SCS

1980) ripens seeds a month earlier than most strains of shrub lespedeza, thus adapting it to the mountains and more northerly areas of the South (Vogel 1974).

Seeds of these strains have been marketed, but production has been so erratic that seed supplies can be scarce or nonexistent. Some problem exists in maintaining seed supplies of pure strains, apparently because of cross-pollination.

**Flowering and fruiting.** The flowers are loosely arranged on elongate racemes and are mostly rose-purple, with gradation to white in some variants (Ohwi 1965; Rehder 1940;Straussbaugh and Core 1964). The chasmo-gamic flowers may be self- or cross-pollinated (Clewell 1966;Crider 1952; Ohwi 1965). Honey bees (*Apis mellifera* L.), bumble bees, and other insects are necessary for pollination (Crider 1952; Graetz 1951).

Time of flowering and fruiting varies among species and strains, but it is also controlled by the latitude where the plants are grown. Flowering occurs mostly in July and August but will begin in June in Mississippi and as late as September in Maryland. The brown fruits are 1-seeded indehiscent legumes (pods) that mature mostly in late September and October (Vogel 1974) (figure 1). The legumes fall to the ground when ripe, and most of them are down by early winter (Crider 1952).

A light seedcrop may occur the first year from 1-year-old transplants, and good seedcrops can be expected each succeeding year (Crider 1952). Seeds of shrub lespedeza are pale brown to olive and copiously flecked with purple. Seeds of Thunberg lespedeza are solid dark purple (Musil 1963) (figure 1). Seeds of lespedeza have little or no endosperm (figure 2).

**Collection of fruits; extraction and storage of seeds.** Shrubs lespedeza seeds are most commonly harvested with a combine as soon as the fruits are ripe and moderately dry. The combined material, which includes stems, intact legumes, and hulled seed, is air-dried and then cleaned to separate seed and legumes from the stems and inert matter. Seeds that remain in their legumes can be hulled by running them again through a combine or through a huller-scarifier and then should be cleaned (Vogel 1974).

Seed yields may exceed 560 kg/ha (500 lb/ac) (Byrd and others 1963), but more commonly yields range from 336 to 447 kg/ha (300 to 400 lb/ac) (Vogel 1974). The number of cleaned seeds is about 187,000/kg (85,000/lb) for common shrub lespedeza (Crider 1952; Straussbaugh and Core 1964; Vogel 1974); 140,000/kg (64,000/lb) for ‘Natob’ bicolor (Crider 1952; Vogel 1974); and 154,000 to 159,000/kg (70,000 to 72,000/lb) for Thunberg lespedeza (Straussbaugh and Core 1964; Vogel 1974).

Seeds are stored at 10 °C and 40% relative humidity. They may be stored either hulled or unhulled, but seeds stored in the hull remain viable longer than hulled seeds. Length of viability varies with harvest years and storage treatment, but seeds have been viable after 20 years of storage (Vogel 1974).

**Figure 1—Lespedeza, lespedeza; legumes (above) of *L. bicolor*, shrub lespedeza (left) and *L. thunbergii*, Thunberg lespedeza (right); and seeds (below) of *L. bicolor*, shrub lespedeza (left) and *L. thunbergii*, Thunberg lespedeza (right).**

**Figure 2—Lespedeza thunbergi, Thunberg lespedeza: longitudinal section through a seed.**
**Pregermination treatments.** A high percentage of shrub lespedeza seeds have hard seedcoats and should be scarified before planting. Mechanical scarification is the preferred method. A huller-scarifier is one machine used for this purpose (Vogel 1974). About 50% of the seeds cleaned in a hammermill will be scarified. Fifty percent scarification allows a good stand to become established the first year but holds some seeds dormant for germination the second year. This could help assure stand establishment in case of failure or poor establishment the first year (Vogel 1974). Seeds can also be scarified by immersion in concentrated sulfuric acid for 30 minutes, followed by washing and drying (Crider 1952). The acid treatment causes less damage to older brittle seeds than does mechanical treatment (Vogel 1974).

**Germination tests.** Germination tests can be made by placing seeds between blotters in a petri dish, in a rolled towel (either horizontally or vertically), or in sand or soil and holding them at temperatures of 20 °C for 16 hours and 35 °C for 8 hours for each day. Light is not required, but it has been used with no effect on germination. First counts of germinated seeds are made at 7 days and last counts at 21 days. Percentage germination is similar for all 3 species; the average is about 76%. Seed purity is 95% or higher (Vogel 1974).

**Nursery practices.** Seeds should be broadcast in large quantities—11 to 16 kg/ha (10 to 14 lb/acre)—on a firm seedbed lacking weeds (USDA SCS 1980). Inoculation with a specific Rhizobium strain is recommended at the time of planting (USDA SCS 1980). When growing seedlings for transplanting, rows should be spaced 0.9 to 1.2 m (3 to 4 ft) apart and planted with 39 to 66 seeds/m (12 to 20 seeds/ft) of row. Seeds inoculated with group 4 (cowpea) inoculant are sown in shallow furrows and covered 6 to 13 mm (1/4 to 1/2 in) deep. Mid-spring is the ideal time for seeding. The time interval for seeding starts in the spring at the last expected frost date and continues thereafter for about 6 weeks. Seeds are treated with tetramethethylthiuram disulfide (thiram) for fungus control. About 95% of the 1-year-old seedlings are usable. For producing wildlife food, direct seeding in the field is more popular than transplanting seedlings (Crider 1952; Vogel 1974). Optimal growth occurs in well-drained, non-acidic soils (USDA SCS 1980).

For producing wildlife food, direct seeding in the field is more popular than transplanting seedlings (Crider 1952; Vogel 1974). Optimal growth occurs in well-drained, non-acidic soils (USDA SCS 1980)).
Other common names. leadtree, zarcilla, popinac, koa haole, tantau.

Growth habit, occurrence, and use. The genus *Leucaena* includes about 50 species of trees and shrubs that are native to Central America and southeast Asia. Leaves, legumes (pods), and young seeds of at least 4 *Leucaena* species have been used by humans for food since the time of the Mayans (Brewbaker and others 1970). *Leucaena—Leucaena leucocephala* (Lam.) de Wit.—the most widespread member of the genus, originated in Mexico and Central America (Brewbaker and others 1972) but is now considered pantropical. It is found throughout the West Indies from the Bahamas and Cuba to Trinidad and Tobago and has become naturalized in southern Texas and southern Florida; it also has been planted in California (Little and Wadsworth 1964). The species was introduced to Puerto Rico and the Pacific Islands during the Spanish colonial era and to Hawaii about 1864. It invades cleared areas and forms dense thickets, either as a shrub or small tree up to 10 m in height (Takahashi and Ripperton 1949). This species is evergreen when moisture is not a limiting factor. Strains of leucaena can be categorized as one of two types: the “common” (or “Hawaiian”) and the “giant” (or “Salvadorian”) (Brewbaker and others 1972). The common type, representing the strains most commonly naturalized outside of the species’ native range, is a drought-tolerant, branchy, abundantly flowering, and aggressive shrub or small tree. The Salvadorian type is an erect tree that attains heights up to 20 m (Brewbaker and others 1972; NAS 1984). In many parts of the world, the species is considered a weed.

*Leucaena* is used for a variety of purposes, including timber, fuelwood, forage, and organic fertilizer. It is planted as a shade tree for coffee, cacao, and other cash crops; for soil fertility improvement; erosion control; and site preparation in reforestation (Neal 1965; NAS 1984; Parrotta 1992; Whitesell 1974). The light reddish heartwood is easily worked but is of low to medium durability. It is used for light construction, boxes, and particleboard. The wood is considered a promising source of short-fiber pulp for paper production. The protein-rich leaves and legumes are widely used as fodder for cattle, water buffalo, and goats. The protein content of dry forage ranges from 14.0 to 16.2% (Oaks and Skov 1967). Depending on variety, the protein consists of 19 to 47% mimosine (Brewbaker and others 1972), an amino acid that can cause weight loss and ill health in monogastric animals such as pigs, horses, rabbits, and poultry when leucaena fodder comprises more than 5 to 10% (by weight) of the diet. Ruminants (cows, buffalo, and goats) in most parts of the world (except for Australia, Papua New Guinea, and parts of Africa and the Pacific) have stomach microorganisms that render mimosine harmless.

Flowering and fruiting. Flowering phenology varies widely among varieties and with location. The common type varieties flower year-round, often beginning as early as 4 to 6 months after seed germination. The giant varieties flower seasonally, usually twice a year. The spherical, whitish flower heads are 2.0 to 2.5 cm in diameter and are borne on stalks 2 to 3 cm long at the ends or sides of twigs (Parrotta 1992). The fruits, generally produced in abundance from the first year onward, are flat, thin legumes that are dark brown when ripe; they measure 10 to 15 cm long and 1.5 to 2.0 cm wide. A legume contains 15 to 20 seeds (Parrotta 1992). The seeds are small (8 mm long), flat, teardrop-shaped, shiny, and dark brown with a thin but fairly durable seedcoat (figures 1 and 2). The seeds are usually released from dehiscent legumes while still on the tree, although unopened or partially opened legumes may be carried some distance by wind. The legumes are commonly eaten by and pass through the digestive tracts of livestock, which appear to be important dispersal agents in pastures.
Collection, extraction, and storage. Legumes may be collected from branches when ripe, before dehiscence; they should be sun-dried and then threshed to release seeds. Threshing is commonly done by beating the dried legumes in cloth bags. There are about 17,000 to 24,000 clean seeds/kg (11,000/lb) (Parrotta 1992). Unscarified seeds will remain viable for more than 1 year when stored under dry conditions at ambient temperatures and up to 5 years stored at 2 to 6 °C. Dried, scarified seeds will remain viable for 6 to 12 months (van den Beldt and others 1985; Daguma and others 1988; Parrotta 1992).

In Hawaii the larvae of a recently introduced beetle—Araecerus levipennis Jordan—can destroy the seed. At times, virtually all of the legumes in certain stands are infested (Sherman and Tamashiro 1956). Seeds should be fumigated as soon as possible after collection to kill the larvae. Because of the uncertain status of methyl bromide at this time, local extension authorities should be consulted about an appropriate fumigant to use.

Pregermation treatments. Although seeds may be sown without scarification, mechanical scarification (abrasion with sandpaper or clipping the seedcoat) or either of the following 2 treatments are used to ensure more rapid and uniform germination (Parrotta 1992): (a) immersion in hot water (80 °C) for 3 to 4 minutes followed by soaking in water at room temperature for up to 12 hours or (b) soaking in concentrated sulfuric acid for 15 to 30 minutes. Scarification may be followed by inoculation with nitrogen-fixing Rhizobium bacteria (mixed with finely ground peat) after coating the seeds with a gum arabic or concentrated sugar solution. Pre-sowing inoculation of seeds facilitates good field establishment in soil devoid of effective rhizobia strains.

Germination tests. Germination rates are commonly 50 to 98% for fresh seeds (Daguma and others 1988; NAS 1984). Scarified seeds germinate 6 to 10 days after sowing; unscarified seeds germinate 6 to 60 days after sowing (Parrotta 1992). Germination in leucaena is epigeal.

Nursery practice. Leucaena seeds germinate on or near the soil surface and should not be planted deeper than 2 cm (3/4 in). Nursery media should be well-drained, have good nutrient and water-holding capacity, and have a pH between 5.5 and 7.5 (van der Beldt and Brewbaker 1985). Light shade is recommended during the first few weeks of seeding development, and full sun thereafter (Parrotta 1992). Taproot development is rapid in young seedlings. Seedlings generally reach plantable size (height of 20 cm or 8 in) in 2 to 3 months. Plantations may be established by direct seeding (Francis 1993) or by planting container seedlings, bare-root seedlings, stem cuttings (2 to 5 cm in diameter).
References

**Other common names.** highland doghobble, doghobble, switch ivy, fetterbush.

**Growth habit, occurrence, and uses.** Drooping leucothoe—*Leucothoe fontanesiana* (Steud.) Sleum.—as its common name implies, has a graceful, arched habit (Bridwell 1994). The plant is a broad-leaved, evergreen shrub, 1 m tall, with a spread of 1.2 to 1.8 m (Halfacre and Shawcroft 1975). Drooping leucothoe spreads by underground stems and can produce impenetrable thickets (Halfacre and Shawcroft 1975). These dense thickets have often hindered hunting from horseback, ensnaring both dogs and horses, hence the common names “doghobble” and “fetterbush.” This species occurs naturally in moist wooded areas along the Appalachian Mountains of the United States, from Virginia to Georgia and Tennessee (Ingram 1961). In its native habitat, drooping leucothoe occurs as an undergrowth accompaniment to taller shrubs such as rhododendron (*Rhododendron* L. spp.) or mountain-laurel (*Kalmia latifolia* L.) (Melvin 1981). Drooping leucothoe is a robust, hardy shrub that can be cultivated in USDA Hardiness Zones 5 to 8. However, a cool, shady, well-drained site must be selected for the southern landscape (Dirr 1990).

The species is best suited for landscape use in lightly shaded sites with moist soil that is high in organic matter (Ingram 1961). Typically, the plant is utilized as an understory shrub to complement other understory plants that have a leggy habit (Dirr 1990). Drooping leucothoe can best be used as a cover on shady banks and is especially effective in mass plantings (Dirr 1990). An additional quality that increases the value of this plant in the landscape is its rich, lustrous, dark green foliage, which becomes reddish bronze in autumn and eventually turns bronze-purple in winter, thus providing seasonal interest (Halfacre and Shawcroft 1975; Odenwald and Turner 1987). No geographic races or hybrids have been described currently in the literature.

**Flowering and fruiting.** White, waxy, urn-shaped flowers are borne on small, pendant, axillary racemes in May and scent the air with a pungent fragrance (Dirr 1990; Odenwald and Turner 1987). Although individual flowers are small (0.6 cm long), they are clustered along 5.0- to 7.5-cm-long racemes and provide a striking contrast to the dark green foliage (Dirr 1990).

**Collection of fruits, seed extraction, cleaning, and storage.** Capsules and seeds ripen in mid- to late autumn and can be collected at that time (Wyman 1953). Capsules are removed from the plant and lightly beaten, then rubbed to open them completely (Dirr and Heuser 1987); then, seeds are shaken from the capsules. Viability can be poor if seeds are not graded rigorously. Seeds are quite small (figures 1 and 2). When dried to a moisture content of 3% and cleaned, pure seeds averaged 22,900/g (650,000/oz) (Blazich and others 1991). Seeds will remain viable if stored dry at room temperature and used within 2 years (Wyman 1953).
Glenn and others (1998) reported that seeds will remain viable for several years if stored in a sealed container at –18 or 4 °C. This suggests that the seeds are orthodox in storage behavior.

**Germination tests.** There are no prescribed methods for official tests of this species, but the seeds germinate readily without pretreatment (Dirr and Heuser 1987; Fordham 1960). Seeds of drooping leucothoe require light for germination (Blazich and others 1991). Blazich and others (1991) conducted a 30-day germination study utilizing seeds from a native population of plants growing in Henderson County, North Carolina. Seeds were germinated at 25 °C or an 8/16 hour thermoperiod of 25/15 °C with daily photoperiods of 0, 1/2, 1/2 twice daily, 1, 2, 4, 8, 12, or 24 hours. The cool-white fluorescent lamps utilized as the light source provided a photosynthetic photon flux (400 to 700 nm) of 35 μmol/m²/sec (2.8 klux). For both temperatures, no germination occurred during the 30-day test period for seeds not subjected to light. At 25 °C, increasing photoperiod increased percentage germination values of 60 and 68% occurring by day 24 for the 12- and 24-hour photoperiods, respectively. The alternating temperature of 25/15°C enhanced germination when light was limiting. At this temperature, germination ≥85% was reached by day 27 for photoperiods ≥2 hours. Germination is epigeal.

**Nursery practice.** Typically, the germination medium is kept at 24 °C via bottom heat (Bir 1987). Seeds are sown on the surface of a steam-pasteurized medium, such as pinebark sifted through a 6-mm-mesh (0.25-inch-mesh) screen. They are irrigated slightly and the surface of the germinating medium is thereafter never allowed to dry completely (Bir 1987). One recommended practice is to fertilize seedlings at the first true leaf stage with a half-strength solution of a 15:45:5 (N:P2O5:K2O) fertilizer (Bir 1987). After 2 weeks, the seedlings are then fertilized with a full-strength solution applied weekly until they are transplanted into liner flats or pots (Bir 1987). Drooping leucothoe can also be propagated vegetatively by rooting stem cuttings (Dirr and Heuser 1987). The species roots readily from cuttings taken during the months of June through December without a need for exogenous auxin application (Dirr and Heuser 1987).

Cupressaceae—Cypress family

Calocedrus decurrens (Torr.) Florin

incense-cedar

William I. Stein

Dr. Stein is a forest ecologist emeritus at the USDA Forest Service’s Pacific Northwest Research Station, Corvallis, Oregon

Other common names. California incense-cedar, pencil cedar, pecky cedar.

Growth habit, occurrence, and uses. Incense-cedar was once classified as the only species in the genus Libocedrus native to the United States (Harlow and others 1979; Little 1979), but recent taxonomic changes have included it as 1 of 3 species in the genus Calocedrus Kurz. Regional genetic variation within incense-cedar is small, but 12-year growth of trees from southern California was less than that of trees from more northerly regions (Rogers and others 1994). Recognized cultivars under the former classification include L. decurrens cv. aureovariegata Beissner, L. decurrens cv. columnaris Beissner, L. decurrens cv. compacta Beissner, and L. decurrens cv. glauca Beissner (Harrison and Dallimore 1966; Rehder 1940).

Mature trees of this evergreen conifer vary in height from 15 to 46 m and from 0.3 to 2.13 m in diameter (Jepson 1910; Sargent 1961; Sudworth 1908). A maximum circumference of 12.9 m (van Pelt 2001) and a maximum height of 68.6 m have been reported (Stein 1974). Young trees generally have dense pyramidal to columnar crowns; older trees are characterized by more open, irregular crowns; rapidly tapering trunks with buttressed bases; and deeply furrowed and ridged bark.

The range of incense-cedar spans about 15 degrees of latitude, from the southeastern slopes of Mount Hood in Oregon southward within and adjacent to the Cascade, Siskiyou, coastal, and Sierra Nevada ranges to the Sierra de San Pedro Martir in northwestern Mexico (Griffin and Crickfield 1976; Sudworth 1908). It extends eastward from the coastal fog belt to arid inland parts of central Oregon, northern California, and westernmost Nevada. In elevation, incense-cedar is found from 50 to 2,010 m in the north and from 910 to 2,960 m in the south (Peattie 1953; Powers and Oliver 1990; Sudworth 1908). Incense-cedar grows on many kinds of soil and is one of the most prominent conifers on serpentine soils. Typically, it is a component of mixed conifer forest and may make up as much as 50% of the total stand (Powers and Oliver 1990).

Trees are harvested primarily for lumber and for round or split wood products. The wood is variable in color, durable, light, moderately soft, uniformly textured, easy to split and whittle, and finishes well. Incense-cedar is also used as a pulp additive and for making a variety of specialty items, the best known being the wooden pencil (Betts 1955; Panshin and others 1964). Boughs, particularly those bearing staminate cones, are harvested commercially for decorations (Schlosser and others 1991), and young trees are a minor component of the Christmas tree trade.

First cultivated in 1853, ornamental specimens with shapely crowns have grown well in many places outside of their native range in the Pacific Northwest—in New England and in the mid-Atlantic region of the United States and western, central, and southern Europe (Edlin 1968; Harrison and Dallimore 1966; Jelaska and Libby 1987; Sargent 1961). Within its native range, incense-cedar is commonly planted for highway landscaping, screenings, and home-site improvement.

Young incense-cedars are sometimes browsed extensively (Stark 1965), but in general, the species rates low to moderate in value as wildlife browse (Longhurst and others 1952; Sampson and Jespersen 1963; Van Dersal 1938). Its seeds are eaten by small mammals (Martin and others 1951) but are not a preferred food of chipmunks (Tevis 1953). Dense understory incense-cedars provide an important source of cover and food for overwintering birds in the western Sierra Nevada (Morrison and others 1989).

Flowering and fruiting. Yellowish green staminate flowers develop terminally on twigs as early as September even before the current year’s cones on the same twigs have opened (Stein 1974). These flowers, 5 to 7 mm long, are prominently present "…tingeing the tree with gold during..."
the winter and early spring..." (Sargent 1961). The inconspicuous pale yellow ovalate flowers also develop singly at tips of twigs. Flowering has been reported to occur as early as December and as late as May (Britton 1908; Hitchcock and others 1969; Mitchell 1918; Peattie 1953; Sargent 1961; Sudworth 1908), but it is not clear how well observers distinguished between flower appearance and actual pollen dissemination. Unopened staminate flowers and open or nearly open ovulate flowers were present on branches collected in the first week of April west of Klamath Falls, Oregon (Stein 1974).

Individual cones (figure 1), each containing up to 4 seeds, are scattered throughout the crown, and mature in a single growing season. As they ripen, their color changes from a medium green to a yellowish green or yellow tinged with various amounts and shades of brown. During opening, the cone becomes reddish brown and acquires a purplish cast. Insect-attacked cones are among the first to change color. Generally, cones of many color shades are found on a tree as opening commences.

Seed dispersal may extend over a lengthy period, from late August through November or later (Fowells and Schubert 1956; McDonald 1992; Mitchell 1918; Powers and Oliver 1990; Sudworth 1908). For example, in 1937 and 1940, respectively, 11 and 32% of the seed had fallen by early October at 1 or 2 California locations, yet 47 and 66% of the total fell after November 11 (Fowells and Schubert 1956). Cutting tests have shown that 14 to 65% of the naturally dispersed seeds appear sound, with higher values coincident with heavy crops (Fowells and Schubert 1956).

The oft-repeated generalization that incense-cedars bear some seeds every year and abundant crops frequently (Betts 1955; Mitchell 1918; Sudworth 1908; Van Dersal 1938) has not been confirmed by systematic observations made in 3 locations. During a 35-year period on the Stanislaus National Forest in California, incense-cedars bore a heavy or very heavy crop in 7 of those years, a medium crop in 11 years, and a light crop in 17 years (Schubert and Adams 1971). On the Challenge Experimental Forest in central northern California, there were 1 medium to heavy and 9 light to very light crops in 24 years (McDonald 1992). During 15 years on the South Umpqua Experimental Forest in southwest Oregon, there were 2 abundant crops, 1 medium crop, and 12 years with light or no crops (Stein 1974). Generalized statewide reports for California and Oregon show that incense-cedar cone crops are often light and that there is wide geographic variability in crop abundance (Schubert and Adams 1971). During years when crops are reported as light or a failure, scattered cones, even an occasional heavily loaded tree, may be found somewhere.

Flowers and young cones may be damaged or killed occasionally by adverse climatic factors, and squirrels cut some mature cones (Fowells and Schubert 1956). Losses are also caused by sawflies (Augomonoctenus libocedrii Rohw.), juniper scale (Carulaspis juniperi Bouche), and leaf-footed bugs (Leptoglossus occidentalis Heidemann) that feed on developing cones and seeds (Furniss and Carolin 1977; Koerber 1963).

**Collection of cones.** Cones are generally hand-picked from standing or felled trees. Stripping cones or using a cone rake will expedite collection because cones hang dispersed over the crown. The ideal time for collection is the short period when cleavages appear between the scales of many cones on a tree. If large quantities of seeds are needed, both collecting them from plastic sheets spread beneath or enclosing the tree and vacuum-harvesting seeds from the ground merit consideration. Dispersed seeds should be collected promptly to minimize heat damage. To facilitate later seed cleaning, foliage intermixed with cones or seeds should be removed during collection or shortly afterward, before it dries and crumbles.

Cones are normally handled and transported in partly filled open-mesh sacks that facilitate cone expansion and air exchange. Good aeration should be provided around each sack to keep the cones from overheating during storage.

**Extraction and storage of seeds.** To maintain high seed viability, cones should not be exposed to high temperatures. Under warm, dry conditions, cones will air-dry outdoors or indoors in 3 to 7 days if layered thinly in trays or on sheeting or tarps. Turning or stirring layered cones will...
facilitate drying and opening. They may also be kiln-dried at 27 °C or lower (Lippitt 1995).

Seeds separate readily from well-opened cones; moderate tumbling or shaking is helpful. Whether done by improvised methods or in commercial machines, tumbling or shaking should be done gently, preferably at less than 27 °C, because seedcoats of incense-cedar are thin and easily broken.

The winged seeds are about 2.5 cm long and nearly one-third as wide (figure 2). Although appearing to have only 1 wing, each seed actually has 2 wings—a long, wide wing extending lengthwise beyond the seed on one side and a narrow, much shorter wing barely merging alongside the first from the opposite side. The wings are persistent and project past the narrow radicle end of the seed rather than from the cotyledon end as in many other conifers (figure 3).

The persistent wings should be left intact. When seeds are run through mechanical de-wingers, the narrow radicle ends may break off along with the wings. This type of damage was the probable cause of the very low viability observed in some lots of de-winged seeds. Damaging effects should be evaluated before using any proposed hand or mechanical de-winging technique.

Small particles of debris can be removed from among winged seeds by screening. Sensitive adjustment of an air stream or gravity separator will permit further cleaning and adequate separation of empty from full seeds with wings intact. Purities of 85 to 98% or more have been obtained (Lanquist 1946; Lippitt 1995; Rafn 1915; Toumey and Korstian 1942).

Thirty-five liters (1 bu) of cones weigh 18 to 23 kg (40 to 50 lbs) and yield from 0.45 to 1.36 kg (1 to 3 lb) of seeds (CDF 1969; Tilloton 1925; Toumey and Korstian 1942). A minimum of 14,110 and a maximum of 63,930 seeds/kg (6,400 and 29,000 seeds/lb) were found among 55 samples from northern California weighed by Show in 1918. More recent collections indicate that seeds per weight values differ by seed zone (Lippitt 1995):

Figure 2—Calocedrus decurrens, incense-cedar: each seed has 2 wings, a long, wide wing on one side (right) and a narrow, much shorter one on the other side (left).

Figure 3—Calocedrus decurrens, incense-cedar: longitudinal section showing the radicle located at the narrow end of the seed.

Small particles of debris can be removed from among winged seeds by screening. Sensitive adjustment of an air stream or gravity separator will permit further cleaning and adequate separation of empty from full seeds with wings intact. Purities of 85 to 98% or more have been obtained (Lanquist 1946; Lippitt 1995; Rafn 1915; Toumey and Korstian 1942).

Thirty-five liters (1 bu) of cones weigh 18 to 23 kg (40 to 50 lbs) and yield from 0.45 to 1.36 kg (1 to 3 lb) of seeds (CDF 1969; Tilloton 1925; Toumey and Korstian 1942). A minimum of 14,110 and a maximum of 63,930 seeds/kg (6,400 and 29,000 seeds/lb) were found among 55 samples from northern California weighed by Show in 1918. More recent collections indicate that seeds per weight values differ by seed zone (Lippitt 1995):
The viability of incense-cedar seeds can also be determined by a tetrazolium test (AOSA 2000). The preparation sequence involves removal of wings from dry seeds followed by soaking in water at room temperature for 6 to 18 hours (overnight). Shallow longitudinal cuts are then made on both ends of the seed to expose the embryo. Cut seeds are immersed in a 1% tetrazolium solution and kept in darkness for 6 to 18 hours at 30 to 35 °C. Seeds having a completely stained embryo and a completely stained endosperm are considered viable. Viability determined by the tetrazolium test reveals the seeds’ maximum potential and generally is somewhat higher than indicated by a germination test.

Nursery practice and seedling development. Soil fumigation of outdoor beds to combat damping-off and other diseases may or may not be necessary before sowing incense-cedar seeds. Maintenance or replacement of endomycorrhizal fungi is of concern if beds are fumigated. Spring-sowing is now most common even though fall-sown seeds germinated earlier and more uniformly than those sown in the spring and resulting seedlings grew larger in the first season if they escaped damage by late spring frosts (Show 1930). An intermediate approach is to prepare seedbeds in the fall to facilitate early sowing in February or March. Before sowing, seeds are usually stratified naked or in a moist medium at 2 to 5 °C for 30 to 60 days (Lippitt 1995). Well-timed spring-sowings of unstratified seeds have produced satisfactory crops (Show 1930; Stein 1974), but results are less certain. Some spring-sown seeds may hold over to produce seedlings the following spring (Show 1930).

The winged seeds are usually hand-sown in rows. They should be covered about 6 to 12 mm (1/4 to 1/2 in) deep (Show 1930). Burlap mulch proved satisfactory to keep seedbeds moist (Show 1930); sawdust or other mulch material and frequent sprinkler irrigation are currently used. Incense-cedar can readily be grown in containers to plantable size in one season. Containers about 15 cm (6 in) deep with a volume of 165 to 215 cm³ (10 to 13 in³) are recommended. The seedlings may be started about February in a greenhouse and moved outdoors after 4 to 8 weeks or they may be germinated and grown entirely outdoors.

Germination is epigeal and the radical emerges from the narrow winged end of the seed (figure 4). Young seeds usually have 2, rarely 3, cotyledons (Harlow and others 1979). Leaves about 1.2 cm (0.5 in) long develop along the epicotyl (figure 5). On the first branches, awl-shaped transitional leaves grade into the normal scalelike leaves (Jepson 1910). Seedlings grow 5 to 20 cm (2 to 8 in) tall in the first season and develop a well-branched root system. Young seedlings are fairly resistant to frost and drought (Fowells and Stark 1965; Pharis 1966; Stone 1957). They are preferentially attacked by cutworms, however, and need protection from damping-off (Fowells 1940; Fowells and Stark 1965; Show...
160 to 215 seedlings/m² (15 to 20/ft²) are used for 2+0 stock. Tree percents range from 20 to 75 (Show 1930; Stein 1974). Generally, 2+0 bareroot seedling stock is used for outplanting, but 1+0, 1+1, 2+1, and 1+2 transplants have also been used. Some of the target sizes now used for producing stock include 1+0 (stem caliper 3 mm and top length 13 cm), 2+0 (stem caliper 3.5 cm and top length 20 cm), and 1+1 (stem caliper 4 mm and top length 25 cm).

Outplanting in the spring proved best in long-ago tests (Show 1930) and continues to be favored.

Incense-cedar also can be reproduced from cuttings started in November (Nicholson 1984), and responds better than most conifers to cell and tissue culture (Jelaska and Libby 1987).

1930; Stein 1963). In the north-central Sierra of California, they grew about as well unshaded as with one-fourth shade (Show 1930). In current practice, both bareroot and container seedlings are grown without shade. They should be watered regularly but not to excess. Beds may be weeded entirely by hand or with mechanical and chemical assistance.

Seedbed densities of 270 to 325 seedlings/m² (25 to 30/ft²) are satisfactory for producing 1+0 stock. Densities of 160 to 215 seedlings/m² (15 to 20/ft²) are used for 2+0 stock. Tree percents range from 20 to 75 (Show 1930; Stein 1974). Generally, 2+0 bareroot seedling stock is used for outplanting, but 1+0, 1+1, 2+1, and 1+2 transplants have also been used. Some of the target sizes now used for producing stock include 1+0 (stem caliper 3 mm and top length 13 cm), 2+0 (stem caliper 3.5 cm and top length 20 cm), and 1+1 (stem caliper 4 mm and top length 25 cm).

The genus *Ligustrum*—the privets—includes about 50 species native in eastern Asia and Malaysia to Australia, with 1 species occurring in Europe and North Africa (Bean 1978; Rehder 1940). Privets have been widely distributed and cultivated outside of their indigenous distributions, and many varieties and cultivars are recognized (Bailey 1947; Bean 1978; Ohwi 1965; Rehder 1940). At least 4 species have naturalized in the United States, several over broad geographic regions (table 1). European, or common, privet is widely naturalized in eastern North America. California privet has been planted from coast to coast in the southern United States and has naturalized extensively in the Southeast.

The privets are deciduous or evergreen shrubs or small trees ranging from 2 to 12 m in height (table 2). Maximum heights reported in the United States are 7.8, 24.9, and 12.8 m, respectively, for California, Chinese, and Japanese privets (AFA 1996). Growth form ranges from compact dense shrubs to small trees with slender spreading branches. Privets grow readily in many kinds of soil (Bailey 1947; Bean 1978; Meikle 1958) and in moisture regimes ranging from very dry to stream-side and floodplain (Lee and others 1991; Seymour 1982). They establish on roadsides, sand dunes, open and closed woodlands, tree borders, and other disturbed areas (Bailey 1947; Radford and others 1968; Seymour 1982; Wilson and Wood 1959).

**Sources:** Little (1979), Rehder (1940), Wilson and Wood (1959), Vines (1983).
The privets are valued for landscape shrubbery because of their handsome white flowers and dark green foliage; ready establishment; and resistance to insects, dust, and air pollution (Bailey 1947; Howe and Woltz 1981). California privet grows well even in the spray of salt water (Bailey 1947). Japanese privet is an excellent evergreen shrub for shaping into hedges, screens, or topiary (distinctive shapes such as globes or animals) (Vines 1983). Glossy privet is an evergreen tree suited for growing in narrow areas, making it a fine choice for a street or lawn tree. Several privets have been used as garden hedges, but their innumerable, fibrous roots are invasive and may impoverish adjacent flower beds (Meikle 1958).

Privets are also useful as wildlife habitat, windbreaks, and erosion-control plantings. Although the lengthy availability of fruits and seeds indicates that they are not generally relished by wildlife, some consumption by birds has been observed (Martin and others 1951; Van Dersal 1938; Vines 1983).

Flowering and fruiting. The terminal panicles bearing privet flowers range from 3 to 20 cm long and are usually somewhat narrower in width than length (Bean 1978). The flowers are small, perfect, always a shade of white, and usually fragrant. However, the fragrance of some privet flowers may be considered “objectionable at close quarters” (Bean 1978). Summer is the main flowering period, but timing and duration vary by species (table 3). There is evidence that Japanese privet seedlings require winter chilling to stimulate blooming (Morita and others 1979).

The fruits are 1- to 4-seeded berrylike drupes with membranaceous to stony endocarps about 4 to 10 mm long (figures 1 and 2; table 2). Fruits ripen from September to November (table 3) and those of some species often remain on the panicles into winter (Rehder 1940). Ripened fruits generally range in color from dark blue to black. The fruits in some varieties of European privet, however, are not black: *L. chlorocarpum* (Loud.) Schelle has green fruits; *L. leuco-carpum* (Sweet) Schelle, white fruits; and *L. xanthocarpum* (G. Don) Schelle, yellow fruits (Bean 1978).

According to incidental observations, privet species produce seedcrops almost annually, but systematic records of crop size and occurrence are not available (Dirr and Heuser 1987).

Collection, extraction, and storage. Ripe privet fruits may be stripped from panicles by hand in the fall or early winter. If the fruits are already dry, they can be stored uncleaned, but prompt cleaning is generally better. Seeds can be separated from fresh or remoistened pulp by running the fruits with ample water through a macerator. For some privet species, particular care must be taken during cleaning to ensure that their soft-coated seeds are not damaged (figure 1).

Privet seeds are relatively small and vary in size and weight by species (table 4). In one sampling, seeds of European privet constituted 54% of fruit biomass on a dry-weight basis (Lee and others 1991).

Storage of cleaned European privet seeds in ordinary dry conditions was recommended long ago (Chadwick 1935), but little has been reported on the success of this practice. It seems likely that their longevity could be prolonged by closed storage at cool temperatures or even at –18 °C, which has proven satisfactory for many tree species that tolerate low moisture content.

Pregermination treatments and germination tests. Fresh privet seeds that have been cleaned will germinate in 60 days without stratification (Heit 1968; Dirr and Heuser 1987). Stored seeds, however, require 30 to 60 days of cold stratification at 0 to 5 °C to induce prompt germination (Chadwick 1935; Dirr and Heuser 1987; Heit 1968; Shumilina 1967). Fifteen days of warm stratification at 18 to 20 °C or alternating warm and cold stratification were suc-
Successful treatments on some seedlots in Russia (Shumilina 1967). Some germination may occur in lengthy stratification. Best germination results have been obtained by running tests for 60 days at 10 °C for 16 hours/day and 30 °C for 8 hours (Heit 1968). In Australian tests, optimum constant germination temperature for fresh seeds of glossy privet was 15 °C and for Chinese privet, 20 to 25 °C (Burrows and Kohen 1983). Germination of European privet seeds ranged from 88 to 92% in tests conducted in New York (Heit 1968). Germination is epigeal (figure 3), and light is not needed for germination.

Viability of seeds can also be determined by a tetrazolium (TZ) staining test as recommended by the International Seed Testing Association (ISTA 1996). Privet seeds should be soaked in water for 18 hours at 20 °C, then cut transversely at the distal end and longitudinally with a scalpel or razor blade to expose the embryo, followed by immersion in a 1% TZ solution for 20 to 24 hours at 30 °C. Those seeds with the embryo and all nutritive tissue stained red are considered viable.

Nursery practice. Fall-sowing is advisable for best seedling production, maximum growth the first year, and less early seedling losses (Heit 1968). Fresh, cleaned privet seeds germinate readily when sown in the fall. In spring sowings, seeds from storage may require 1 or 2 months of stratification to ensure uniform germination with minimum hold-over (Bailey 1947; Dirr and Heuser 1987). One- or two-year seedlings are used for outplanting.

Vegetative propagation is the preferred method for producing privet species or varieties and ensuring continuation of the same characteristics in successive generations. All species are easy to root from vegetative stem cuttings and many growers root them in outside beds (Bailey 1947; Dirr and Heuser 1987; Keever and others 1989; Regolinski 1984). Non-dormant cuttings should be rooted under a mist system to prevent them from drying out during summer months. Dormant cuttings can be set in rows outdoors during the fall, winter, or early spring. Shoot and root initiation and growth of dormant and non-dormant privet cuttings can be accelerated, even doubled, by appropriate applications of growth regulators, bleach, and wetting agents (Dirr and Heuser 1987; Yang and Read 1991, 1992; Rauscherova and Tesfa 1993). Pre-emergence herbicides did not affect stock plants of glossy privet or the rooting of cuttings taken from them (Cantanzaro and others 1993).

Growth habit, occurrence, and uses. The genus *Lindera*—spicebush—comprises 80 species of deciduous or evergreen trees or shrubs (Huxley and others 1992). The 3 deciduous species (table 1) native to the United States are generally found in moist woodlands, usually as understory plants. Common spicebush is a deciduous shrub to 4.6 m tall; it has been cultivated since 1683 and is valuable for wildlife food and environmental plantings. The fruits are eaten by grouse (*Bonasa umbellus*), quail (*Colinus virginianus*), pheasants (*Phasianus colchicus*), and other birds (Grimm 1957). The dried fruit has been used as a substitute for allspice and the leaves, bark, and fruit for their medicinal properties as a treatment for coughs and colds (Bremness 1994; USDA Forest Service 1948). Both common and Japanese spicebushes (table 1) are grown and sold by the horticultural industry for their spring flowers and aromatic and colorful fall foliage (Huxley and others 1992). Common spicebush is commonly used as a root stock for cuttings of Japanese spicebush (Boyle 1997). Pondberry and bog spicebush are both much less abundant than common spicebush and have much smaller ranges (table 1). Pondberry was listed as an endangered species by the USDI Fish and Wildlife Service in 1986.

Flowering and fruiting. The yellow to yellow-green flowers of spicebush are dioecious or polygamous and appear from March to May before the leaves (Fernald 1950). The fruits, which begin developing in May, are red drupaceous berries ripening in August or September (Rehder 1940). Each fruit contains a single seed that is light violet-brown with flecks of darker brown (figures 1 and 2). The affects of sun and shade habitats on flower production, sex ratio, and resulting population dynamics of common spicebush have been studied by Niesenbaum (1992) and Cipollini and others (1994).

Collection of fruit; extraction and storage of seeds. Spicebush fruits should be collected at maturity from August to October (Van Dersal 1935). Seedcrops can vary from year to year. Seed collectors must pay careful attention to fruit maturity to ensure that seeds are collected at the optimal time and to limit loss of seeds to birds. Fruits collected before maturity had seeds with low or no viability (Boyle 1997). The fresh fruits should be de-pulped in water, the pulp floated off, and the seeds thoroughly air-dried (Brinkman and Phipps 1974). Seeds should not be stored or planted still within the berry. There are about 10,000 seeds/kg (4,550/lb). Forty-five kilograms (99.2 lb) of fruits

of common spicebush yields about 7 to 11 kg (15 to 25 lb) of seeds (Brinkman and Phipps 1974). Common spicebush seeds usually lose their viability soon after maturity, but storage at 1 to 5 °C will prolong viability for 1 to 2 years (Boyle 1997; Murphy 1997).

Pregermination treatment. Common spicebush has a dormant embryo that responds to warm incubation for 30 days at 25 °C followed by 90 days of moist stratification at 1 to 5 °C (Schroeder 1935). Good results were also obtained with 120 days of moist stratification in peat or sand at 5 °C (Barton and Crocker 1948; Brinkman and Phipps 1974). In another test, Olney (1960) reported best results after stratifying seeds for 105 days in sand at 5 °C. Dirr and Heuser (1987) believe that seeds of Japanese spicebush should be stratified cold for 3 months, and they also reported 85 to 90% germination with 3 months of cold stratification for common spicebush. Seeds of pondberry sent to the USDA Forest Service’s National Tree Seed Laboratory in 1993 (in accordance with a permit issued by the USDI Fish and Wildlife Service for the purpose of germination and propagation) were germinated using 3 different stratification schemes. Each scheme (table 2) produced good results. Some seeds germinated during the 28-day warm cycle of the warm-cold stratification scheme. This would suggest that the dormancy present in common spicebush may not be present to the same degree in pondberry.

Germination tests. Tests may be made in moist peat or sand at a constant temperature of 25 °C, or at alternating temperatures of 30 °C in the day and 20 °C at night. Germination rate may be 70 to 100% in 14 to 28 days for treated seeds, and total germination should range from 85 to 100% (Brinkman and Phipps 1974). Tetracyclom staining and excised embryo tests will also provide accurate testing information. Excised embryos can develop into seedlings if they are not damaged during excision.

Nursery practice. Common spicebush seeds should be sown in the fall and mulched over winter. The mulch should be removed in April or May before germination begins. Stratified seeds may be sown in the spring. From 70 to 80% of the sound seeds can be expected to produce seedlings (figure 3). Spicebush grows well in sandy soils of pH 4.5 to 6.0 (Brinkman and Phipps 1974; Laurie and Chadwick 1931).

Hamamelidaceae—Witch-hazel family

Liquidambar styraciflua L.
sweetgum

Franklin T. Bonner

Dr. Bonner is a scientist emeritus at the USDA Forest Service’s, Southern Research Station
Mississippi State, Mississippi

Other common names. redgum, American sweetgum, sapgum, bilsted.

Growth habit, occurrence, and use. Sweetgum—Liquidambar styraciflua L.—is found on a variety of sites from Connecticut and southeastern Missouri, south to central Florida and southeastern Texas. It also occurs in scattered locations from Mexico south to Nicaragua (Kormanik 1990) and is considered by some to be a very promising species for the American tropics (McCarter and Hughes 1984). This large deciduous tree reaches heights of over 45 m and diameters of 1.2 m at maturity (Brown and Kirkman 1990). Sweetgum has some value for pulp, lumber, and veneer. The seeds are eaten by many species of birds (Van Dersal 1938), and the tree is planted as an ornamental. It was first cultivated in 1681 (Bonner 1974).

Sweetgum exhibits quite a bit of variation over its wide natural range (McCarter and Hughes 1984; McMillan and Winstead 1976; Wells and others 1991; Williams and McMillan 1971). Minor differences in germination and seedling growth and morphology have been reported, but there is no strong evidence for distinct geographic races in the species.

Flowering and fruiting. The small, greenish, monoeccious flowers bloom in March to May. The pistillate flowers are borne in axillary, globose heads that form the 22- to 35-mm-diameter multiple heads of small 2-celled capsules (figure 1). The lustrous green color of the fruiting head fades to yellowish-green or yellow as maturity is reached in September to November (Bonner 1974; Vines 1960). At the point of color change, moisture content of the fruit head should have dropped below 70% (Bonner 1972). The beaklike capsules open at this time, and the small, winged seeds (figures 2 and 3), 1 or 2 per capsule, are dispersed. Empty fruiting heads often remain on the trees over winter. Fair seedcrops occur every year and bumper crops about every 3 years. The flowers are susceptible to late spring freezes that can greatly reduce seedcrops. Crop reductions of up to 44% have also been reported from damage by seed bugs—Leptoglossus oppositus (Say)—in North Carolina (Ebel and Summerville 1983). Some trees have been known to flower and bear fruit 4 and 5 years after planting (Mohn and Randall 1970), but good crops are not common until the trees reach 20 to 30 years of age (Bonner 1974).

Collection and extraction. Mature fruit heads must be picked from standing trees or logging slash before seed dispersal. The best indicator of maturity is the fading of
their green color. Fruit heads should be dried to completely open the capsules so that the seeds can be extracted by shaking or tumbling. Drying may be done indoors on well-ventilated screen racks or outdoors on plastic or canvas sheets in the sun (Bonner 1987). Indoor drying takes approximately 7 to 10 days, whereas outdoor drying in typical fall weather in the South should require only 3 to 5 days. The fruit heads should be stirred daily, and those dried outdoors should be covered at night and during rain (Bonner 1987). Canvas sheets are preferred over plastic, as plastic tears easily and also tends to promote condensation of moisture (Robbins 1984).

Fruit heads picked prematurely may be ripened in moist storage at 5 °C for about a month (Bonner 1970). The fruit heads should then be spread to dry until they open and release the seeds. This operation may take longer than drying fruits that were picked when mature, and the seed yields may be less.

Leaves, twigs, and the sawdust-like aborted seeds can be removed most easily with hand screens and laboratory blowers or with air-screen cleaners, depending on the size of the lot (Bonner 1974). Round-hole screens are best for this job, but variations in seed size due to geographic origin or weather during maturation may require a variety of hole sizes (Bonner 1987). Two passes through an air-screen cleaner should produce seedlot purities of 98%. Seedlots may then be upgraded by removing empty seeds with laboratory blowers or by flotation in water (Bonner 1987). From mostly southern collections, the following yield data were obtained (Bonner 1974):

- Weight per volume of air-dried fruiting heads (1 sample) was 11 kg/hl (or 8.5 lb/bu).
- Weight of cleaned seeds per volume of fruiting heads (3 samples) was 1.0 kg/hl (0.8 lb/bu).
- Number of seeds per fruiting head (144 samples) was 56.
- Range in number of seeds per weight (40 samples) was 143,300 to 217,000/kg (65,000 to 98,400/lb), with an average of 180,000/kg (82,000/lb).

In Mississippi, there were significantly more seeds per fruiting head on trees in the Mississippi River flood plain than on trees from other parts of the state (Kearney and Bonner 1968).

Storage. Sweetgum fits in the storage category of orthodox seeds, that is, its seeds can be stored for a number of years at low temperatures and moisture contents (Bonner 1994). Seed moisture should be maintained in the 5 to 10% range. For storage periods of 5 years or less, temperatures should be kept at 0 to 5 °C; for longer storage, subfreezing temperatures (−18 °C) should be used (Bonner 1987). The ultimate storage potential of the species is not known, but seeds stored at −18 °C for 14 years at the USDA Forest Service’s Forestry Sciences Laboratory, in Mississippi State, Mississippi, lost no viability.

Pregermination treatments. Sweetgum seeds exhibit what can be described as only a shallow dormancy (Nikolaeva 1967). Studies of geographic variation in sweetgum have shown that stratification requirement increases from south to north (Wilcox 1968; Winstead 1971), but even the southernmost sources will respond to stratification with increased germination rates (Bonner and Farmer 1966; Rink and others 1979). Moist stratification at 3 to 5 °C for 2 to 4 weeks should produce timely germination both in the laboratory and in nurseries (Bonner 1987). Satisfactory treatment has also been achieved by soaking the seeds for 14 to 20 days in water at 3 to 5 °C (Bonner 1974). Older seeds from storage may not require as much stratification, especially if they have been stored above freezing. Stratification of lots stored longer than 7 years under such conditions should be cut in half (1 to 2 weeks) (Bonner 1987).

Germination tests. Satisfactory tests may be obtained with either constant or alternating temperature regimes, but alternating temperatures of 20 °C at night for 16 hours, and 30 °C in the day for 8 hours are recommended for official
Light is not absolutely necessary for germination of stratified seeds (Bonner 1967), but it is normally used in all testing. Tetrazolium staining (Bonner and Gammage 1967), radiography (Belcher and Vozzo 1979), and the excised embryo method (Bonner and Gammage 1967; Flemion 1948) also provide reliable tests of viability. Germination is epigeal (figure 4). For moisture testing, duplicate samples of 4 to 6 g each should be dried for 17 ± 1 hour at 103 ± 2 °C (ISTA 1993), or electric meters can be used for rapid measurements (Bonner 1981).

Nursery practice. Stratified seeds should be broadcast or drilled in the spring to achieve an initial seedling density of 100 to 160/m² (9 to 15/ft²) (Barham 1980). Aluminum powder may be mixed with wet stratified seeds at a rate of 15 ml/45 kg of seeds (4 tablespoons/100 lb) to achieve easy flow in seeders (Bonner 1974). The seeds should be sown on the surface and lightly into the soil with a roller. A 6- to 12-mm (1/4- to 1/2-in) mulch of sawdust, sand, or chopped pine straw should be applied (Bonner 1974; Coleman 1965; Vande Linde 1964), although some nurseries have reported better results with wood fiber mulches at rates of 1,400 to 2,900 kg/ha (1,250 to 2,600 lb/ac) (Barham 1988).

Ornamental cultivars of sweetgum are usually propagated vegetatively. Cuttings taken in early June will root, and budding is common also (Dirr and Heuser 1987).

Figure 4—Liquidambar styraciflua, sweetgum: seedling development at 2 and 30 days after germination.

Magnoliaceae—Magnolia family

*Liriodendron tulipifera* L.
tuliptree

Franklin T. Bonner

Dr. Bonner is a scientist emeritus at the USDA Forest Service's Southern Research Station, Mississippi State, Mississippi

Other common names. yellow-poplar, poplar, tulip-poplar, white poplar, whitewood.

Growth habit, occurrence, and uses. Tuliptree—*Liriodendron tulipifera* L.—occurs naturally throughout the eastern United States from Vermont and southern Michigan south to Louisiana and north-central Florida (Little 1979). It grows under a variety of climatic conditions from sea level to 1,370 m elevation in the Appalachian Mountains and to 300 m in the northern part of its range. This large deciduous tree is among the tallest in the eastern United States and reaches considerable age: tuliptrees planted by George Washington still grow at Mount Vernon (Griswold 1999). It can attain heights of 61 m and diameters of 2.4 to 3.7 m at maturity (Beck 1990). The wood is very valuable for lumber and veneer. It is a good honey tree and is planted extensively as an ornamental. Tuliptree has been cultivated since 1663 (Bonner and Russell 1974).

Flowering and fruiting. The large, perfect, greenish-yellow flowers of tuliptree open from April to June (Little and Delisle 1962). The fruit is an elongated cone composed of closely overlapped carpels that are dry, woody, and winged (figure 1). Each carpel (samara) contains 1 or 2 seeds (figure 2). The cones turn from green to yellow to light brown as they ripen; they mature from early August in the northern part of the range (Guard 1943) to late October in the South (Bonner and Russell 1974). As the mature cones dry on the trees, they break apart and the samaras are scattered by the wind. Peak dissemination occurs in October and November, but a few samaras fall as late as the following March (Carvell and Korstian 1955; Whipple 1968). In South Carolina, seedfall is usually at least 90% complete by early December (Goebel and McGregor 1973).

Good seedcrops occur almost every year; failures, as well as bumper crops, occur infrequently. In North Carolina, 1 large tree produced 29,000 sound seeds, and seedfall of 1.5 million seeds/ha is not uncommon (Beck 1990). In a South Carolina study, 1 of 5 seedcrops was heavy (Goebel
hives of honey bees (Apis mellifera L.) in their orchards to produce filled seed yields as high as 75% (Houston and Joehlin 1989). Some seed orchard managers have placed controlled pollinations in seed orchards to increase seed production; results have been varied. Yield data from various locations (table 1) suggest that samaras from southern trees are larger than those from northern trees.

Collection of fruits. Mature cones may be picked by hand from standing trees or from logging slash. In the southern United States, cone maturity is first indicated by the color changes in cones from green to yellow, which usually occurs in late October. At this point, cone moisture content is still high (over 60% of fresh weight), and cones must be handled carefully to avoid overheating. Maturity is assured when cones turn dark brown in color, but dry weather can quickly cause cones in this condition to break apart and scatter the samaras (Bonner and Russell 1974). Cones may be collected from logging slash felled as much as 4 weeks before natural maturity, but they must be dried slowly to allow maturation of the seeds. One way to do this is to wait 2 to 3 weeks after felling to pick the cones (Bonner 1976b). Cones and seeds may also be shaken onto canvas or plastic sheets from standing trees in early winter. A mechanical shaker was used successfully to dislodge cones from trees in West Virginia; from 9 to 95% of cones were collected from individual trees without apparent damage (Cech and Keys 1987). Cones from the upper two-thirds of the crown yield more full seeds than cones from the lower one-third (Guard and Wean 1941), probably because of inefficient pollination in the lower branches.

Cones should be spread out to dry immediately after collection. Drying sufficient to separate the samaras usually requires 7 to 20 days, depending on temperature, humidity, and cone moisture content (Bonner and Russell 1974). Cones may be dried more quickly by using the forced air systems of cone tray driers, but no heat should be applied.

Extraction, cleaning, and storage of seeds. Thoroughly dried cones can be broken apart by hand by shucking, flailing, or treading, or by running them through a hammer mill or macerator (Bonner and Russell 1974; Steavenson 1940). Tuliptree seeds can be de-winged in macerators or in out de-bearers. After wing fragments and fruit axes are removed with air-screen cleaners, many of the empty (unfertilized) seeds can be removed with gravity tables or aspirators (Bonner and Switzer 1971). By this process, filled seed percentages of 6 to 10% can be upgraded to 60 or 65%. There are 80 to 100 samaras/cone (Bonner and Russell 1974). Yield data from various locations (table 1) suggest that samaras from southern trees are larger than those from northern trees.

Tuliptree seeds are orthodox in storage behavior; they may be stored at low seed moisture contents (6 to 10%) and low temperatures (2 to 5 °C). No long-term storage data are available, but storage for several years under these conditions without loss of viability is common (Bonner and Russell 1974). Excellent results have also been reported for 3 to 4 years of moist storage in outdoor soil pits (Paton 1945; Williams and Mony 1962) or in drums of moist sand held in cold storage at 2 °C (Bonner and Russell 1974).

Pregermination treatments. Seeds to be sown in the spring and seeds taken from dry storage need pretreatment to overcome dormancy. The traditional method of moist storage in well-drained pits or mounds of mixed soil, sand, and peat, can successfully overwinter seeds for as long as 3 years (Bonner and Russell 1974; Williams and Mony 1962) or in drums of moist sand held in cold storage at 2 °C (Bonner and Russell 1974). Cold, moist stratification in plastic bags, both with or without peat moss or other media, in refrigerators for 60 to 90 days is widely used (Bonner and Russell 1974). Recommended temperatures for cold stratification are a constant 2 to 5 °C (Adams 1968; Bonner and Russell 1974), but alternating weekly temperatures of 0 and 10 °C (Chadwick 1936) or 2 and 12 °C (Boyce and Hosner 1963) have also been successful. Percentage and rate of germination of some sources of tuliptree have been significantly increased by soaking seeds in solutions of the potassium salt of gibberellic acid (GA₃) (100 and 1,000 mg/liter), but no practical application of this method has been reported (Bonner 1976a).
period of 28 days (AOSA 1993). If empty seeds have not been removed from test samples, germination percentages will be quite low because of the naturally low proportion of filled seeds common in this species. Germination of the filled seeds should be good, however; percentages of 80 to 90% are common (Bonner and Russell 1974). Seeds ungerminated at the end of a test should be cut to determine if any embryos are present. Viability can also be estimated by tetrazolium staining (ISTA 1993) and by radiography (Belcher and Vozzo 1979; Kaeser and Boyce 1962; Taft 1962). Germination is epigeal (figure 3).

Nursery practice. Untreated seeds may be sown in the fall, but stratified seeds must be used for spring sowing. Seeds may be broadcast at rates of 25 to 75 kg/m² (1 to 3 lb/ft²) of bed space or sown in rows 20 to 30 cm (8 to 12 in) apart at a rate of 80 to 100 seeds/m (24 to 30 ft) (Bonner and Russell 1974). Bed densities of 110 seedlings/m² (10/ft²) are recommended (Williams and Hanks 1976). To assure proper bed density, the proportion of filled seeds must be known before sowing. The seeds should be covered with 6 mm (¼ in) of soil or 12 to 25 mm (½ to 1 in) of sawdust and beds should be shaded for 1 to 2 months from the start of germination (Bonner and Russell 1974). Fumigation with MC-33 (67% methyl bromide plus 33% chloropicrin) was recommended for control of cylindrocladium root rot—Cylindrocladium scoparium Morg. (Affeltiranger 1969). Because of the uncertain status of methyl bromide at this time, local extension authorities should be consulted about an appropriate fumigant to use.

Occurrence and growth habit. This evergreen hardwood species, the sole representative of its genus in North America, is considered a link between the chestnuts (Castanea) and the oaks (Quercus) (McMinn 1939). Tanoak (also known as tanbark-oak)—Lithocarpus densiflorus (Hook. & Arn.) Rehd.—has flowers that resemble those of the chestnuts, but acorns that resemble those of the oaks. Tanoak is found from just north of the Umpqua River in southwestern Oregon southward throughout the coastal ranges to the eastern end of the Santa Ynez Mountains in western Ventura County, California. Its range then extends eastward to near Grants Pass, Oregon, and the lower slopes of Mt. Shasta, and then intermittently southward along the western slopes of the Sierra Nevada in Mariposa County, California (Griffin and Critchfield 1972).

A striking characteristic of the tanoak species is that, throughout its range, the tree form is found where moisture is present—from the soil, from fog, or from high relative humidity (McDonald and Tappeiner 1987). Another characteristic of the species is that shade is a requirement, but the amount varies by reproductive mode. Seedlings from acorns need shade to become established and grow. Sprouts from root crowns, which are often found in burned or otherwise severely disturbed areas, grow best in full sunlight, but only until the crowns close. From then on, and whether from acorns or sprouts, only toplight is needed. Indeed, full sunlight is then deleterious.

Because partial shade is necessary, tanoak is often found in dense stands, usually in mixture with several conifer and hardwood species. Pacific madrone (Arbutus menziesii Pursh) and Douglas-fir (Pseudotsuga menziesii (Mirb.) Franco) are its most common associates. The species is particularly abundant in a belt surrounding the redwood forest in northern coastal California and in Yuba and Butte Counties in the Sierra Nevada (Sudworth 1908). But even though abundant, it is reported to “never” form pure stands (Jepson and others 1911). However, extensive pure stands of tanoak, 40 to 50 years old, have developed in northwestern California after logging and fire (Thornburgh 1994). Tanoak often forms part of the overstory, but almost always in a codominant position. It is rarely found in a dominant position, except possibly when part of a ragged overstory with Douglas-fir. Because tanoak cannot withstand sudden exposure to full sunlight, leaving scattered mature tanoak trees after heavy logging is a sure way to cause blighted tops and decreased acorn production (McDonald and Tappeiner 1987). Tanoak also is abundant in the understory in intermediate and suppressed crown positions.

As a codominant forest tree, tanoak has a crown that is shaped much like the tapering cone of its principal conifer associate, Douglas-fir. It has a long, straight bole, often clear of branches for 9 to 24 m (Roy 1974); narrow crown; and slender upright branches. Leaning, forking, and crooked trees are uncommon. In stature, tanoak is best described as medium in height, with most trees growing to a range of 13 to 47 m.

Tanoak also has a recognized shrubby form—L. densiflorus var. echinoide (R. Br.) Abrams—and possibly another, unrecognized one. The recognized form is reported in northern California in Shasta, Siskiyou, and Trinity Counties and on the lower slopes of Mt. Shasta. In these areas, it is restricted to rocky exposed ridges intermixed with tanoak trees that reach heights of 17 m in protected spots (Griffin and Critchfield 1972). They also describe the shrubby form at the end of the species’ southern range in the Sierra Nevada. Roy (1974) states that the northern California variety has a typical shrub form, low stature, and “small, thin” leaves. The unrecognized form is found in the northern Sierra Nevada in a narrow elevational band just above that occupied by the tree form (McDonald and Litton 1987; McDonald and others 1989). Here large clumps, often flattened by heavy snow, are found with stems straggling downslope for 5 m or more (Tappeiner and others 1990). In addition, the thick, dark-green leaves of these plants are as
large or larger than those of the tree form. Sudworth (1908) was doubtful about classifying this shrubby form as a variety. He stated that it was "...not to be worth of separation because it is connected with the larger tree forms by numerous intermediate ones."

Use. The hard, strong, fine-grained wood has a long but intermittent record of use in California and Oregon (Huber and McDonald 1992). It has been used for flooring, railcar decking, paneling, veneer, plywood, gunstocks, pallets, crossties, baseball bats, pulpwood, and fuelwood (EDA 1968). In the past, tannin was extracted from the bark for tanning heavy leathers (Jepson and others 1911), hence its common names.

Flowering and fruiting. Tanoak produces flowers in the spring and irregularly during autumn. Most flowers arise from the axils of new leaves, occasionally from buds at the base of year-old leaves (Peattie 1953). April, May, and June are the months of heaviest flowering. Pistillate (female) flowers form at the base of the catkins, below the spike of the staminate (male) flowers (Hickman 1993). The pistillate flowers are 5 to 10 cm long and form crowded clusters in such profusion as to conceal the foliage. Initially, their color is white, eventually turning to yellow.

The fruit is a fairly large, heavy acorn (figures 1 and 2), maturing at the end of the second season, and numbering about 242/kg (110/lb) (Mirov and Kraebel 1937). Acorns are borne singly or in clusters of 2 to 4. They ripen in September to November, with peak fall occurring when the relative humidity is low, often when a dry north wind is blowing (McDonald 1978). Generally, the first and last acorns to fall are unsound. The minimum seed-bearing age (from root-crown sprouts) is 5 years, with abundant production occurring after age 30 to 40. On a good site in northern California, annual records showed that, during a 24-year period (1958–1981), tanoak produced 4 medium to heavy and 9 very light to light seedcrops (McDonald 1992). The number of acorns per mature tree is reported to range between 3,900 and 110,000 (Tappeiner and others 1990). Soundness of just-fallen acorns varies from 49 to 79%.

Collection, extraction, and storage. Although it fairly "rains acorns" in the fall of a bumper seed year, few remain by spring. Consumption by a host of birds, rodents, and other animals typically is heavy. In a study in several clearcuttings in southwest Oregon (Tappeiner and others 1986) and in studies in northwestern California (Thornburgh 1994), consumption after 3 annual sowings was over 99%. Many acorns are killed by insolation and freezing but, even though they are embryo-dead, they are still prime food for birds, rodents, and other animals. Acorns should be gathered during or shortly after the time of maximum seed fall, preferably from shady, covered locations. Those that fall in an exposed environment overheat and become embryo-dead in a few days, possibly even in a few hours. Freezing temperatures also kill embryos of exposed acorns (McDonald 1978).

Tanoak acorns generally are stored without the cups. Storage for any length of time can be risky. Death or germination often occur. Acorns can be stored in sacks in cool shaded places or in plastic bags containing a small amount of moist material at temperatures just above freezing. The most effective and efficient technique is to place sound acorns in wire containers buried near the planting site and covered with soil and dead leaves. Here, they stratify in tune with the local environment and produce tiny radicles in the
spring. Seeding germinated acorns almost guarantees a high initial seed-to-seedling ratio.

**Pregermination treatments.** Stratification in moist peat moss at temperatures just above freezing is all that is needed to give high germination values (97% and 6 days). Germination is hypogeal (figure 3).

**Germination.** Acorn position is a major influence on germination and subsequent seedling survival and development. Reversing polarity (placing acorns so that the pointed end is up) enhances the speed and completeness of germination, as well as seedling development. In a test in a conventional plantation (clearcutting) with 840 acorns placed point-up and 772 point-down, germination was 53% for point-up acorns and 21% for point-down acorns. Germination rate was 12 versus 41 days, respectively (McDonald 1978). Early germination, however, subjected the just-emerged (7-day-old) seedlings to late spring frost and many were frozen. It is of interest that 75% of these seedlings eventually sprouted from the root crown, but with multiple stems. Perhaps shade from the outer stems provides the inner stems with a more favorable environment and is at least part of the reason for this phenomenon.

**Nursery practice.** Tanoak seedlings are difficult to grow in the nursery. The emergent seedling produces a fast-growing taproot that quickly exceeds the depth of conventional containers and should not be clipped.

**Seeding care.** Extensive trials on a good site in northern California involved seeding sound acorns and out-planting container seedlings. In spite of the utmost care in site preparation—yearly removal of competing plants, loosened soil at each seed spot, careful seeding, use of acorns known to be viable when seeded, rodent protection, fertilization, and irrigation—seedling survival and growth were poor. Survival of 4- and 6-year-old seedlings was about 34% and mean height was 30 cm (12 in). Many plants had multiple stems from repeated dieback and sprouting (McDonald 1978). Most eventually died. The fate of container-grown seedlings that were given extensive care and artificial shading was little better. Survival after 2 growing seasons was 46%; height growth after outplanting was essentially nil (McDonald 1978). Most seedlings eventually died. The clipped taproot did not renew and the seedling’s poorly developed root system did not extend beyond the already loosened soil. When that dried out, the seedlings died. Survival and growth of natural tanoak seedlings is best described as fair and slow, respectively. We cannot grow tanoak seedlings in conventional sunlit plantations. An environment of moderate shade and plentiful organic material seems necessary for survival and establishment of both artificial and natural seedlings. How to achieve consistent and reliable seedling growth remains a mystery.

Occurrence, growth habit, and uses. Honeysuckles include about 180 species of deciduous or evergreen, bushy, scandent, twining, or creeping shrubs, found throughout the Northern Hemisphere, south to Mexico and North Africa, Java, and the Philippines (Huxley 1992). Many species are cultivated for their attractive, often-fragrant flowers and for their ornamental fruits. Some species furnish food and cover for wildlife, whereas others are valuable for erosion control and shelterbelt planting (Brinkman 1974; Huxley 1992). They are valued also for their extreme cold hardiness (Herman and Davidson 1997). Many species introduced in the United States have escaped cultivation and have become naturalized within this century (table 1). Japanese, Amur, and Tatarian honeysuckles are now considered invasive weeds (Luken and Thieret 1997)

Scientific and common names. The nomenclature of honeysuckles has been the object of many revisions over time. Many species were once classified as varieties, and vice versa, making synonyms common. The names currently accepted for species native to, naturalized, or in cultivation in the United States are listed in table 1.

Geographic races and hybrids. Erstad (1991) demonstrated extensive genetic variation between black twinberry plants from various northwestern American provenances. Thirty North American honeysuckles have been assigned varietal status (Kartesz 1994). Among the 74 cultivated honeysuckles reported by the Liberty Hyde Bailey Hortorium (1976), 10 species are of hybrid origin.

Flowering and fruiting. The small, perfect flowers vary from white or yellow to pink, purple, or scarlet. They are borne in axillary pairs or sessile, 6-flowered whorls in terminal spikes or panicles. Time of flowering varies not only among species but also by geographic locality within species (table 2). The attractive fruits are berries, white, red, orange, blue, or black at maturity (table 2). They occur often in coalescent pairs that ripen in the spring, summer, or early fall (figure 1). Depending on the species, each berry contains a few to many small seeds that measure about 4 mm in diameter (figures 2 and 3) (Brinkman 1974; Huxley 1992).

Bountiful seedcrops of Amur and Tatarian honeysuckles are borne nearly every year. No data are available concerning the age that plants must be to produce a good seedcrop. Seeds are dispersed primarily by birds and other animals. Fruits of Amur, Morrow, and Tatarian honeysuckles persist well into the winter (Brinkman 1974).

Collection of fruits. Fruits should be hand-picked or stripped from the branches as soon as possible after ripening to reduce consumption by birds (Brinkman 1974). Belcher and Hamer (1982) advocate flailing pruned branches of Amur honeysuckle inside a large drum as a time-saving method. Although pruned plants do not bloom the following season, greater quantities of fruits are produced from these plants the second year after pruning.

Fruit color is generally used as an indicator of maturity. Cram (1982) reported, however, that the germination rate of seeds of Tatarian honeysuckle collected several weeks prior to the “color-ripe” stage was not significantly different from that of seeds extracted from ripe fruits. It is generally recommended that fruits be collected from isolated plants or

Groups of plants, as honeysuckles are believed to hybridize freely (Brinkman 1974).

**Seed extraction and storage.** Unless seeds can be extracted immediately, fresh fruits should be spread out in thin layers to prevent heating. Extraction is accomplished by macerating the fruits in water and allowing the empty seeds and pulp to float and the viable seeds to sink. Munson (1986) has described the use of modified kitchen and shop implements to facilitate extraction. After a short drying period, seeds are ready for sowing or storage. Data regarding seed yields are presented in table 3.

Honeysuckle seeds are apparently orthodox in storage behavior. Storage of air-dried seeds at room temperature results in loss of viability over several years. One study showed that germination of swamp honeysuckle decreased 20% after 1 year (Brinkman 1974). In another experiment, seeds of Tatarian honeysuckle stored at 15 to 29 °C showed a more or less continuous decrease in viability with length of storage, with negligible germination after 6 years. In contrast, storage of dried seeds in sealed containers at 1 to 3 °C for 15 years resulted in little loss of viability (Brinkman 1974).

**Pregeration treatments.** Seeds exhibit considerable variation in dormancy. Some species have both seedcoat and embryo dormancy, whereas others have only embryo dormancy or lack dormancy entirely. This variability also occurs among different seedlots of the same species (Hartmann and others 2002; Romanyuk 1989). Swingle (1939) reported that 75 to 90 days of cold stratification
(moist prechilling) were needed for Amur honeysuckle, whereas Luken and Goessling (1995) found that seeds of the same species collected in northern Kentucky showed no dormancy and had a rapid drop in viability after dispersal. Cold stratification in moist sand or peat for 60 to 90 days at 4 °C is generally recommended to overcome embryo dormancy. Seedcoat dormancy has been reported repeatedly in hairy and swamp fly honeysuckles but has never been confirmed experimentally. When seedcoat dormancy is known or suspected, Brinkman (1974) recommends that cold stratification be preceded by warm moist stratification for 60 days at 20 to 30 °C (table 4). He indicated that without such treatments, germination may be prolonged over a period of 6 months or longer.

Germination tests. Germination is epigeal (figure 4), and germination tests can be conducted in flats or in a germinator. Light is not necessary, at least for Tatarian honeysuckle. For most species, alternating temperatures of 30 and 20 °C yield satisfactory results (table 5). Brinkman (1974) reported conflicting results in 2 studies conducted to determine the optimal germination temperature of Tatarian honeysuckle. One study reported that 20 °C or less was required for complete germination, whereas the other reported that 18 to 20 °C was the minimum needed, with the most rapid germination occurring at 25 to 27 °C. Swingle (1939) reported that tests by the USDA Soil Conservation Service (which is now called the Natural Resources Conservation Service) showed no correlation between seed viability, as estimated by cutting tests, and germination rates as measured by germination tests. There are no official testing protocols for honeysuckle species.

Nursery practice and seedling care. Seeds of species of honeysuckle that only exhibit embryo dormancy can be

Source: Brinkman (1974)
sown either broadcast or by drills in the fall, or cold-stratified and sown in early spring. Seeds of species believed to have an impermeable seedcoat as well, however, should be sown as soon as possible after collection to ensure germination the next spring. Nondormant seeds may be sown in the spring without pretreatment. Seeds should be covered with 3 to 6 mm (1/8 to 1/4 in) of nursery soil. Mulching with 5.0 to 7.5 cm (2 to 3 in) of straw prevents excessive drying of the soil and seeds. Germination of Tatarian honeysuckle usually is complete in 40 to 60 days after spring-sowing. This time can be shortened by soaking seeds in water for 2 to 3 days before sowing. About 15% of sown seeds of Tatarian honeysuckle result in usable seedlings. One- or 2-year-old seedlings of this species and Amur honeysuckle are suitable for field planting (Brinkman 1974).

Vegetative propagation of honeysuckles by stem cuttings is also possible. Most species can be propagated readily by softwood, semi-hardwood, or hardwood cuttings (Dirr and Heuser 1987; Hartmann and others 2002).

Other common names.
Brisbane-box, scrub-box, vinegar-tree.

Growth habit, occurrence, and uses.
Brushbox is a straight-boled evergreen tree that obtains heights of 35 to 45 m (18 m in Hawaii) (Carlson and Bryan 1959; Francis 1951; Maiden 1904). It is native to the eastern coastal region of Australia and has become naturalized throughout India and Africa as well as in California, Florida, and Hawaii (Bailey 1906; Little and Skolmen 1989; Streets 1962). It has been planted for timber and for ornamental purposes in Hawaii (Little and Skolmen 1989). The wood grown in Hawaii is moderately resistant to decay and termites, whereas wood grown in Australia is considered to be very resistant to both. In Hawaii, the wood is used for pallets, flooring, and pulp chips, whereas in other regions it is used extensively for construction, shipbuilding, bridges, railway crossties, and pallets (Little and Skolmen 1989). This species is a hardy ornamental and shade tree with handsome foliage (Streets 1962).

Flowering and fruiting.
The white brushbox flowers appear in clusters of 3 to 7 on short branches at leaf bases and the backs of leaves. Individual flowers are about 2.5 cm wide. The fruits are bell-shaped capsules 1 to 1.5 cm in diameter and light green to brown in color (Little and Skolmen 1989; Neal 1965). Individual seeds are flat, elongated (figure 1), light brown in color, and less than 4 mm long (figure 2). Seeds are produced moderately well at 15 to 20 years of age (Carlson and Bryan 1959). In Hawaii, trees can be found in all stages of the reproductive cycle at any time during the year, depending on the aspect and elevation at which they are growing (Petteys 1974).

Collection, extraction, and storage.
In Hawaii, the capsules are picked by hand when they turn from green to greenish brown in color. They should be spread out on trays or tables to complete the drying process. Once the capsules are dry, simple agitation will separate the seeds from the capsules. There are almost 5 million seeds/kg (2.2 million/lb), but as few as 2 or 3% of these may be viable (Petteys 1974). The seeds are orthodox in storage behavior,
as they have stored well in sealed polyethylene bags at low moisture contents and temperatures of –18 to –23 °C (Petteys 1974).

**Germination.** Brushbox is not dormant and no pregermination treatments are necessary for timely germination. Germination of full seeds for one group of samples averaged about 70% (Petteys 1974).

**Nursery and field practice.** Brushbox seeds are mixed with fine soil and the mixture is applied to beds with a fertilizer spreader. Germination usually begins in 10 to 14 days. Mulching and shading are not necessary. Seeds are usually sown from November to March and seedlings are outplanted the following winter at 1+0 stock. Bed densities of 215 to 320 seedlings/m² (20 to 30/ft²) are recommended. Seedlings must be treated and planted with care to minimize the high mortality common to this species (Petteys 1974).

### References

Bush lupine, a large, fast-growing but short-lived shrub found in the northern coastal scrub of California, has been planted for dune stabilization in northern California (Davidson and Barbour 1977; Gadgil 1971a,b,c). Inyo bush lupine is not positively distinct from whiteface lupine, and they are often grouped together.

Flowering and fruiting. Flowers are bisexual, irregular, blue, purple, and yellow in racemes. Pauma lupine will bear viable seeds at 1 year of age (Everett 1957). It flowers from April to May (Munz and Keck 1959) and its seeds ripen from May to August (Ratliffe 1974). Whiteface lupine flowers from March to June (Hickman 1993) and its seeds mature from early June to late July.

Collection, extraction, and storage. The legumes (pods) of both Pauma and whiteface lupines pop open when ripe and disperse 2 to 12 seeds (figures 1 and 2). Hence, it is necessary to collect the legumes while the seeds are somewhat green (Ratliffe 1974). Immature legumes can be gently air-dried until they open. The coarse material can be removed by screening. The number of clean Pauma lupine seeds per weight in 2 samples was 39,700 to 52,900/kg (18,000 to 24,000/lb) (Mirov and Kraebel 1937). Information on seed weight is lacking for whiteface lupine; however, for the closely related Inyo bush lupine, the num-

Growth habit, occurrence, and use. The genus *Lupinus* is a large genus of herbs and shrubs that are distributed worldwide (Christofolini 1989). Only 10 to 14 Old World species, all herbaceous, are recognized (Williams and others 1983). New World lupines are more diverse, with 147 species found in North America (USDA SCS 1982), 200 in Mexico, 30 to 40 in Central America, and about 500 in South America (Christofolini 1989). Four shrub species are considered here (table 1). Three species are commonly planted in California. Pauma lupine can reach a maximum height of about 2.5 m (Hickman 1993). As far as can be determined, Pauma lupine was first cultivated in 1928 and has since proved to be valuable as an ornamental plant and for watershed protection and erosion control. Though some plants may live for 10 years, Pauma lupine is generally short-lived (Everett 1957). Whiteface lupine, a more northerly shrub species in California, often reaches a maximum height of 3 m. Since it was first cultivated in 1927, it has been planted for wildlife purposes, watershed protection, and more recently for environmental forestry. Four varieties of whiteface lupine are recognized: *Lupinus albifrons* var. *collinus* Greene; var. *douglassii* (I.G. Agardh) C.P. Sm.; var. *flumineus* C.P. Sm.; and var. *eminens* (Greene) C.P. Sm. (Hickman 1993; USDA SCS 1982).
Germination. Stored seeds of the lupines have hard seedcoats that require pretreatment to induce prompt germination. Seeds of the west Australian blue lupine (*L. angustifolius* L.) became impermeable to water when their moisture content was reduced to 10 to 12% (Quinlivan 1962). Each of 3 treatments—mechanical scarification, a hot water soak, and cold stratification for 72 days at 2 °C—induced prompt germination (Ratliffe 1974). In addition, the hard seeds of this lupine became permeable to water when exposed to simulated surface soil temperature fluctuating between 16 and 60 °C (Quinlivan 1962). Ongoing research on sundial lupine (*Lupinus perennis* L.) suggests that seeds from both the northeastern and southwestern United States germinate poorly (10%) without scarification, but that treatment with concentrated sulfuric acid for 30 to 60 minutes (depending on source of seed) improves germination to near 90%. Preliminary comparisons with bush lupine further suggest that seeds from the 2 species respond similarly to acid treatment.

Germination percentage has been variable for both untreated fresh seeds and pretreated stored seeds (table 2), which may reflect species or population-dependent scarification requirements. Current nursery practices for breaking hardseededness in lupines include nicking, sandpaper scarification, and hot water soaking (Kaplow 1996; Wilson 1996).

Nursery and field practices. Container production of shrubby lupines is somewhat difficult. Young seedlings are susceptible to slug and snail damage. Soil temperatures must be kept low; pot-heating in summer greenhouses may cause major mortality. Root systems are delicate and transplant survival is often low (Kaplow 1996). Wilson (1996) recommended planting seeds directly into large containers and using a well-aerated soil mix. Shrubby lupines may be direct-seeded after scarification to break hardseededness. They do best in poor, rocky, or sandy soils where competition from perennial grasses is minimal.

Other common names.  matrimony vine, desert-thorn, boxthorn, squawthorn.

Growth habit, occurrence, and use.  The wolfberries—Lycium L.—include about 100 species of shrubs native to the temperate and subtropical regions of both hemispheres (Rehder 1940).  Deciduous or evergreen as well as thorn-bearing and unarmed forms occur in the genus.  Species of wolfberry native to the United States tend to be desert shrubs (Benson and Darrow 1954; Wallace and others 1980; Webb and others 1987).  Wolfberries are used as ornamental shrubs because of their showy berries, but they also provide wildlife habitat and watershed protection.  At least 1 species is grown for shelter hedges.  The 2 introduced species—Chinese wolfberry and matrimony vine—have been grown horticulturally for the longest most extensively in this genus.  It is likely that geographic races have developed within widely distributed wolfberry species.  Some botanical varieties may be geographical races.  Hitchcock (1932) mentions apparent racial development in Anderson wolfberry.  Natural hybrids occur where species ranges overlap, as is the case with Anderson wolfberry and Torrey wolfberry (L. torreyi Gray) and Rich wolfberry (Hitchcock 1932).  Information on 5 species (table 1) is included here.

Flowering and fruiting.  The perfect flowers, grading by species from white to lavender, usually bloom in the summer (table 2).  They are followed by bright red (rarely yellow or black) berries (table 3), each with few to many seeds (figures 1 and 2).  Good seedcrops are borne almost every year by matrimony vine (NBV 1946) and probably by other wolfberry species.  Arizona desertthorn produces seed abundantly (Van Dersal 1938).

Collection of fruits; extraction and storage of seeds.  Ripe berries may be picked from the bushes in the fall.  The berries are soft and may be pulped by forcing them through a screen and floating out the pulp (Rudolf 1974).  For extraction on a larger scale, berries may be fermented, mashed in water, and then run through a hammermill equipped with screens of suitable sizes (Glazebrook 1941).  After extraction, the seeds should be dried and stored in sealed containers at 5 °C (NBV 1946; Rudolf 1974), or stratified in moist sand (Glazebrook 1941; NBV 1946).  Stratified seeds of matrimony vine will maintain good viability for 6 months (NBV 1946), but there is no information on long-term storage of dry seeds.  They appear to be orthodox, however, so storage should not be a problem.  Seed data are listed in table 4.

Germination.  Dormancy in wolfberry seeds is variable.  Seed samples of Anderson wolfberry and Arizona desert-thorn germinated well without pretreatment.  They had germination of 68 and 94% (Swingle 1939).  Germination of matrimony vine seeds, however, was hastened and improved by stratification in moist sand for 60 to 120 days at 5 °C.  After cold stratification, the average germination capacity for 19 samples was 74% (Glazebrook 1941; NBV 1946; Rudolf 1974).  These tests were run in sand flats for 30 to 40 days at diurnally alternating temperatures of 30 to 20 °C.  Germination after 18 days was 54%.  Seeds of Rich wolfberry probably would benefit from similar pretreatment,
